THE Lancashire and Cheshire Society for the Permanent Care of the Feeble Minded will hold its annual meeting at the Manchester Town Hall at 3.30 p.m. on Friday, October 21st. Persons interested are invited to attend.

THE West Riding Association of Graduates of the University of Edinburgh will hold its annual general meeting at the Great Northern Station Hotel, Leeds, on Friday, November 4th, at 6.30. It will be followed by the annual dinner, at which Professor Edwin Bramwell, M.D., professor of clinical medicine in the University of Edinburgh, will be the guest of the society. Further particulars can be obtained from the honorary secretary, 33, Manor Row, Bradford.

At a meeting of the Royal Microscopical Society, Hanover Square, on October 19th, at 8 p.m., Dr A. J. Grant will describe a simply made hot plate for flattening preparations. A paper on stereoscopic vision with the microscope will be read by Dr Oskar Heilmann, and Professor J. L. Vonwiller will discuss the application to living organisms of microscopy with incident light.

A MEETING of the Society of Superintendents of Tuberculosis Institutions will be held at 122, Harley Street, Friday, October 21st, at 3 p.m. Dr J. Graves, of Charing Cross, will speak on the surgical treatment of tubercle of the pleura, and Dr Konnon Dunham, Cincinnati, will read a paper on various types of tuberculous lesion, as seen in a dry plate, in the child and the adult, with illustrations.

THE course of lectures at the Royal Institution in November and December will commence on November 1st at 5.15 p.m. with the annual course of three Tyneside lectures which will be delivered by Sir John Herbert Parsons on the subject of Light and Sight. On November 22nd will be the first of four lectures by Sir William Bragg on the work in x-ray crystal analysis. The Christmas lectures for juveniles will be delivered by Professor L. N. da Costa on "Engines," commencing on December 23rd at 3 p.m.

THE St Thomas's Hospital old students' dinner will be held on Friday, October 28th, at 7.30 for 8 o'clock, at Thomas's House, Lambeth Palace Road. The club for students which was opened by the Archdeacon of Canterbury last April. The chair will be taken by Charles Billance, consulting surgeon to the hospital.

THE opening lecture of the series arranged by the Fellowship of Medicine on practical hints on medicine, surgery and the specialties will be given by Sir Humphry Rolleston at the Medical Society's House, 11, Chandos Street, Cavendish Square, W., on Monday, October 17th, at 5 o'clock. The following demonstrations have been arranged by the Fellowship: On October 19th, 4 p.m., Mr. Davenport, Central London Ophthalmic Hospital, October 20th, 3 p.m., Mr. Attwater, Mr. Answorth Davis, Mr. Coote, and Mr. Longhurst, All Saints Hospital, October 21st 3 p.m., Dr. Bernard Myers, Royal Waterloo Hospital, all these lectures and demonstrations are open to members of the medical profession, without fee. An all day course in diseases of children has been arranged from October 17th to 23rd by the staffs of the Laddington Green Hospital and the Victoria Hospital for Children. On October 17th a two weeks course in gynaecology will be given at the Chelsea Hospital for Women. From October 24th to November 5th a series of demonstrations on the diagnosis and treatment of diseases of the eye will be given by the staff of the Royal Eye Hospital, Southwark, at 3 p.m. A two months comprehensive course is in progress at the National Hospital, Queen Square, of which any part may be taken separately. The following courses will take place during November: two practitioners courses, Hampstead General Hospital, October 31st to November 12th, and London Temperance Hospital, November 21st to December 3rd, medicine, surgery, and gynaecology at the Royal Waterloo Hospital, November 14th to December 3rd, diseases of the chest at the Brompton Hospital, November 7th to 12th, neurology at the West End Hospital for Nervous Diseases, November 21st to December 17th, urology at St. Peter's Hospital, November 14th to 26th, proctology at St. Mark's Hospital, November 28th to December 3rd, and venereal diseases, October 31st to November 26th, at the London Lock Hospital. Syllabuses etc., may be had from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

STARTING on October 25th lectures and demonstrations will be given at the Royal Northern Hospital on Tuesdays after noons at 3.15 p.m. There will also be an intensive course in the afternoons during the week November 21st to 25th the subjects to be dealt with include: the epilepsies, tuberculosis of the genito-urinary tract, ringworm, recent work on the acute specific fevers, head injuries, failed forceps cases and acute ear infections. Both courses are free to medical practitioners. Details will appear in our Diary column each week and further information may be obtained from the dean, Royal Northern Hospital, Holloway, N.7.

THE HUNTSMAN Society of London will hold two general discussions before Christmas. The first, on the legal perils of the doctor, will take place on Monday, November 7th at 9 p.m., in Cinders Hall. The second, on baculæ, will follow a dinner at Simpson's Restaurant, Chesham, on December 5th.

THE Society of Public Analysts will hold a meeting on November 2nd at St. Mary's Hospital, Paddington, by invitation of the Pathological Institution there.

THE Liverpool Annual Medical Service will be held in Liverpool Cathedral on Sunday, October 16th at 3 p.m. The Bishop of Chester will be the preacher and the Lord Mayor and Lady Mayoress will attend the collection will be given to the Royal Medical Benevolent Fund. The service has been held each year since the beginning of the century (with the exception of one year during the war). Tickets for the part of the cathedral reserved for the profession may be obtained from the honorary secretary, Dr. John Owen, 13, Rodney Street, Liverpool.

THE council of the Royal Institute of Public Health, in co-operation with Alpine Sports Ltd., has arranged a tour for medical practitioners and their relatives to visit the principal Swiss stations for the treatment of tuberculosis during the Christmas holidays. The party will leave London on Sunday, December 18th and visit Zurich, Chur, Arosa, Davos, and St. Moritz. Christmas Day will be spent at Maloja and other places to be visited include Milan, Montagna and Leysin. It is estimated that the inclusive cost of the tour will be about £23 second class rail, or £28 first class. Further information may be obtained from the honorary secretaries, the Royal Institute of Public Health, 37, Russell Square, W.C.1.

THE Master's Day dinner of the Society of Apothecaries of London was held in the hall of the Society at Blackfriars on October 11th. The Master, Dr. R. Whiteside Statham, I.P., taking the chair. In proposing the first toast of the evening 'The Health of the Master' the Senior Warden, Lieut. Colonel C. T. Stumm, referred to the distinguished connexion of the Statham family with the Society, a point to which the Master subsequently returned. The toast of 'The Royal Colleges' was proposed by the Master in a humorous speech, Dr. Sidney Phillips, replying for the Royal College of Physicians referred to its present situation in space as the centre of a circle of continuous motion, while Mr. F. J. Steward

responded for the Royal College of Surgeons. The toast of 'The Guests' was in the capable hands of the Junior Warden, Dr. H. J. Hott. Sir James Berry, President of the Royal Society of Medicine, replied gently twice in his fellow guest Sir Henry Curtis Bennett, B.C., who, after satisfactorily establishing the claim of the legal profession to the appellation 'learned,' commented on the sympathy for humanity in distress which resulted from the work of both the medical and legal professions. Admiration was generally expressed at the great improvement in the appearance of the handsome hall of the society, as the result of recent cleaning and restoration measures.

THE Grand Council of the British Empire Cancer Campaign, at its meeting on October 10th, made a grant of £500 to St. Mark's Hospital, London, for the continuation of special investigations into cases of cancer. Reports were received on the progress of the organization of the United Lancashire and Cheshire appeal for funds further to develop cancer research at special research centres at Liverpool, Manchester and Chester. The High Commissioner for Australia (Sir Granville Pym, B.C.M.G.) was elected a member of the Grand Council as the representative of the University of Sydney Cancer Research Committee which is affiliated to the campaign. It was reported that the Governor of Queensland (Sir John Goodwin) had become a patron of the Cancer Campaign Committee being formed in that State, and that the Federal and State Governments had each given £500 to the fund.

DR. ARTHUR HASTINGS BOSTOCK has been chosen as the Mayor of Chichester for the ensuing year. He was a member of the City Council some years ago, but not at the present time, so that his choice to be mayor is all the greater compliment. He is surgeon to the Royal Sussex Hospital at Chichester for which a centenary extension scheme is in contemplation. Dr. Bostock has been once home physician to St. Bartholomew's Hospital served as a civil surgeon in South Africa in 1900 and was attached to the P.A.M.C. in France during the war. His father also a medical man was twice mayor (1884 and 1891).

PROFESSOR H. R. KENNEDY, B.C.M.G. who recently retired from the office of medical officer of health for St. Leonards, after thirty three years' service, was entertained on October 8th by the members and officers of the council and friends at a complimentary dinner and was presented with an illuminated address.

DR. W. PRINGLE MORGAN, who recently retired after forty one years of practice at Seaford has been presented at a public meeting with an inscribed silver salver. Mrs. Morgan received a tortoiseshell toilet set, Miss Morgan a gold wristlet watch, and a joint gift to Dr. and Mrs. Morgan consisted of a silver tea service. Dr. Morgan was president of the Sussex Branch of the British Medical Association in 1925.

THE programme of the congress known as the Journées Médicales d'Egypte which is to be held at Cairo from December 15th to 24th will include a variety of discussions on diseases in temperate and tropical countries. There will be sixteen sections—namely ophthalmology, medicine, surgery, bac teriology, urology, gastro-enterology, hygiene, pharmacology, parasitology, dermatology, oto-rhino-laryngology, pediatrics, obstetrics, neurology, tuberculosis and veterinary medicine. Papers will be read on alimentary troubles in infancy, heliotherapy in pulmonary tuberculosis, the treatment of diabetes, the blood groups in biology and medicine, liver abscess, the serology and prophylaxis of leprosy, malaria, trachoma and Malta fever. The languages of the congress will be English, French, German, Italian and Arabic. An international exhibition is being arranged and among the extensions is a visit to Luxor and Assuan. Further details of the congress and the special facilities available for travel may be obtained from the general secretary, Dr. Zeitoun, 32, Rue Gay Lussac, Paris 15.

THIS week's issue of the *Autocar* is greatly enlarged and contains a strand to stand guide to the cars now on view at the Olympia Motor Show. Advance details are given of all the new models for 1928 together with plans showing the position of every exhibit and a price classification of cars.

PROFESSOR T. SHENKIN of Aberdeen University has prepared a new edition of his book *Lost Mortems and Morbid Anatomy* which has been out of print for some time. It will be published during October by Messrs. Faber and Gwyer. The book has been enlarged to make it a textbook of special pathology as well as a manual for use in the post mortem room.

MESSRS. J. AND A. CHURCHILL announce for early publication a volume entitled *Recent Advances in Tropical Medicine*, by Sir Leonard Rogers.

A REVISED and enlarged edition of Dr. Dan McKenzie's *Diseases of the Throat, Nose and Ear* will shortly be published by Wm. Heinemann (Medical Books) Ltd.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Anthology Westcent, London*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London*

MEDICAL SECRETARY, *Medisecra Westcent, London*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams *Bacillus, Dublin*, telephone 4737 Dublin), and of the Scottish Office, 6, Drumshough Gardens, Edinburgh (telegrams *Associate, Edinburgh*, telephone 24361 Edinburgh).

### QUERIES AND ANSWERS

#### MENSTRUAL "UNCLEANLINESS"

DR ROBERT HITCHISON (London, W) writes: I have recently discovered that there exists a belief, even amongst educated persons, that if meat is handled by a woman during her menstrual period decomposition of the meat is apt to result. I should be glad if any of your readers can inform me whether this superstition is at all widespread and, if so, how it arose.

\* \* Some kind of an explanation of how it arose may perhaps be found in Leviticus, chapter 15, verse 19 et seq. The belief that milk may be spoiled if a menstruating woman handles the udder of the cow or the teats is certainly very widespread.

#### "FILLETING"

"J E P" writes: The following is an extract from the church warden's and overseers' account for the year 1680: "Paid for five yd of filleting and for sugar, which was used about setting Peter Smith's leg, 0-0-6." "Filleting" I am told, is a kind of lace and was probably used for a bandage. I should be interested to learn for what purpose the sugar was used. Was it to "stiffen" the bandage?

\* \* This is probably a variant spelling of "filleting," which is synonymous with a bandage. The two small "f's" represent a capital letter. In the *New English Dictionary* we find under filleting:

"2 A woven material for binding, tape, a piece of the same, a band or bandage."

Examples of its use are:

1639 De Gray *Compt Hoisem* 79 'Taken a piece of Filleting and bind it above the Pastern joint

1658 A Fox *Wurtz Surg* II, xxviii 197 'I tied on the rousers two filletes'

There seems no connexion between filleting and lace on record. In any of the dictionaries consulted. It is perhaps suggestive that "fillet" was also, and more commonly, used to denote a bandage, and that one meaning of this word, which is still in technical use, is a thin narrow strip of any material. The *New English Dictionary* has the following:

Fillet b *Carpentry* A narrow strip of wood fastened upon any surface to serve as a support etc. or to strengthen an angle formed by two surfaces.

It is tempting to suppose that this word may have been used for a light splint and the following quotation from Paley's *Natural Theology* supports such an interpretation:

"We cannot hardly help [sic] comparing this (the ligation of the bones) with the binding up of a fracture where the fillet is almost always strapped across for the sake of giving firmness and strength to the bandage."

Sugar may have been used as a poultice. We have known it so used abroad since either alone or mixed with salt, and when mixed with soap it is a popular application for boils. Perhaps it acted as a hypertonic solution when wet. The eighteenth

century surgeon, William Cheselden, used white of egg to stiffen a bandage for fractures, etc., but we have no record of reading of sugar being so employed. As Cheselden states that he got the idea from a bonesetter, the method may have been in use for centuries, handed down as a trade secret, and 1680 was not so very remote from his time.

#### TREATMENT OF FLATULENCE

DR P H COURT (Norton Cuckney, Mansfield) writes in answer to "West Country" (October 1st, p 620), who asked for advice to the treatment of recurrent attacks of gastric and intestinal flatulence, to recommend "Laxol," a French preparation. The makers state that it consists of extracts of intestinal bacteria of bile, together with lactic ferments, and, as a result, Dr Court recommends that it should be given after meals, and that the dose should be from one to six tablets, according to the results obtained.

DR C C ELLIOTT (Leicester), in reply to the inquiry from "West Country," sends the following suggestions: (1) Diet, if oral sepsis is present, (2) give 2 grains of tannic acid with each meal, (3) if still unrelieved, give also colloidal iron of aluminium, two tablets before and two tablets after each meal.

#### INCOME TAX

##### Car Replacement Average Basis

"W L A" replaced his car in 1925 and, owing to the depreciation of the three years' average, has so far received a benefit of one third of that amount. As the assessment for 1927 is based on the 1925 figures he is losing the benefit of the remaining two thirds. The Inspector of Taxes offers to cancel the £69 deduction and allow percentage wear and tear on (apparently) the new car (Section 29, Finance Act, 1926, giving the election to compute the average does not apply).

\* \* In our view the deduction of the 1925 expenses, giving an effective relief of £69 only, can properly be treated as a grant of the "obsolescence" allowance. In that case there is no reason why the depreciation allowance on the new car for 1927 should be reduced. The 1926-27 claim is now out of date. The equities of the case are so strong that the Inland Revenue might reasonably be pressed to deal with it on this basis.

### LETTERS, NOTES, ETC.

#### INSURANCE AGAINST ACCIDENTS TO DEPUTIES

"SHEFFIELD" writes: On inquiry I find that a medical man who employs a locum tenens is liable for accidents (1) under the common law, (2) under the Workmen's Compensation Act. Under the latter Acts if a locum tenens meets with a fatal accident, when so employed the employer may have to pay as much as £300. This year I insured my locum tenens for three years. There were the usual forms to be filled up and a payment of 10s 9d, also a wages book had to be kept showing the wages paid to the locum tenens, and finally I had to fill up a form for the use of the Government Inspector giving particulars of wages paid, costs of board, lodging, etc., at the time of termination of contract, etc. I intend in future to enter this trouble out by only engaging a locum tenens who has insured himself already against all risks.

#### MEDICAL GOLF

THE autumn meeting of the Medical Golf Society was held at Rye on October 8th and 9th, by kind permission. The day was in beautiful order and every arrangement was made for the comfort of the competitors. The thanks of the society are certainly due to the secretary Major Reeves. The dinner and selling sweep were a great success. The results of the competitions were as follows:

Singles v *Dogey*—1st W H Lamplough 1 up 2nd H C 1 down G Dawson and G Hebert tied for third place 2 down 4  
*Fourstones v Dogey*—1st L Bromley and Surgeon Compt 2 down 2  
 1st Lveridg and M S Mason J C Lee and D L tied for second place 3 down  
 The *Canny Rival Cup* was won by J D Gray with the score of 71  
 T A Torrance J W Harrison and M S Mason tied at 73 for place. Won on replay by T A Torrance.

#### BAG FOUND

A BLACK Gladstone bag was picked up and handed to the Rye on August 22nd on the Maidstone Road, Last Station, near the stone. It is 15 in by 9 in, has become almost worn from use and contains various surgical appliances, bandages, etc. Communications should be sent to the Kent County Council, Wrens Cross, Maidstone.

#### VACANCIES

NOTIFICATIONS of offices vacant in universities, medical schools, and of vacant resident and other appointments in hospitals will be found at pages 39, 40, 41, 44 and 45 of our columns, and advertisements as to partnerships and locum tenencies at pages 42 and 43. A short summary of vacant posts notified in the columns appears in the *Supplement* at page 101.

## The Harveian Oration

OR

## GILBERT, BACON, AND HARVEY

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS  
OF LONDON, OCTOBER 18TH, 1927,

BY

SIR WILLIAM HALL-WHITE, K B E, M D LOND,  
M D DUB LI D Ed

CONSULTING PHYSICIAN TO GUY'S HOSPITAL

THERE are two reasons why Harvey should be placed in the select class of really great men. One is, because he discovered that the blood circulates, being compelled to do so by the contraction of the heart, the other—even more powerful—is because he was among the earlier scientists to show the value of properly conducted experiment.

Every man's mind is compounded of what is born within him, modified by impressions received from without. Therefore it is of interest to see who were the men around Harvey who might have influenced him. At Padua there were his teachers, many Harveian Orators have dealt with this part of his life, but I propose to see if any of his own countrymen perhaps without his knowledge, can have helped to mould such of his thoughts as led to his great discovery. I shall make many quotations, but this, I trust, you will pardon—first, because in my argument, it is necessary that the premisses should be precise, secondly, because the language of Bacon is like music to the ear.

Inasmuch as Harvey and Francis Bacon—commonly called Lord Bacon, which is wrong (his titles were Baron Verulam of Verulam and Viscount St Alban)—were contemporaries, we must consider whether it is likely that he swayed Harvey.

## "The Advancement of Learning"

Harvey published his discovery in 1628, and tells us that he had, for many years and more, in his lectures, confirmed "these views by multiplied demonstrations in your presence, illustrated them by arguments and freed them from the objections of the most learned and shrewd anatomists." His first mention of it is in his notebook dated 1616. *The Two Books of Francis Bacon of the Proficiency and Advancement of Learning Divine and Humane*, were first published in 1605 when Harvey was 27 years old twenty-three years before the publication of his discovery and several years before he made it. *The Advancement of Learning*, the first great book in English prose of secular interest" (Church), had many readers for three editions quickly appeared. When his *Instauratio* was issued Bacon sent the King a copy, with a letter saying he thinks it will find many readers "because I hear my former book of the *Advancement of Learning* is well tasted in the Universities here, and the English Colleges abroad and this is the same argument sunk deeper." The *Advancement*, which we thus see was widely read in the years immediately following its publication implores those who wish to delve into the secrets of nature to discountenance mere authority and not blindly to believe what they are told, but to seek knowledge for themselves by observation and experiment. It teaches how properly to use induction, it points out the hopelessness of the false methods of reasoning commonly used. It has much in it about medicine. It is a noble work devoted to the lofty purpose of increasing knowledge. Its language is so beautiful and dignified that it may be placed second to that of Shakespeare.

The first book contains an oblation to James I, because Bacon longed to persuade the King to be interested in learning. In this he failed as he had with Elizabeth.

Passing to the second book I will by direct quotation,\*

\* All quotation unless otherwise indicated are from *The Works of Francis Bacon*, collected and edited by Spedding, Ellis, and Heath (fourteen volumes London 1901). Reference to volume and page is given at the end of these quotations.

try to prove that the *Advancement of Learning*, so immediately popular that Harvey must have known of it, would have appealed to him. Much of the argument is directed to show that a reform of method in the pursuit of knowledge is necessary. Thus

For as things are now if an untruth in nature be once on foot what by reason of the neglect of examination and countenance of antiquity and what by reason of the use of the opinion in similitudes and ornaments of speech it is never called down" (Vol 3 p 331)

"For the handling of final causes mixed with the rest in physical enquiries hath intercepted the severe and diligent inquiry of all real and physical causes to the great arrest and prejudice of further discovery and have brought this to pass that the search for Physical Causes hath been neglected and passed to silence" (Vol 3 pp 337 338)

It being the nature of the mind of man (to the extreme prejudice of knowledge) to delight in the spacious liberty of generalities and not in the enclosures of particularity (Vol 3 p 359)

Where there is much controversy there is at many times little enquiry (Vol 3 p 403)

They listened to their theories and dogmatical and were unperceptive and scornful toward particulars (Vol 3 p 337)

Next listen to a few quotations illustrating Bacon's plea for the experimental method

I find some collections made but commonly with a rejection of experiments familiar and vulgar. For it is esteemed a kind of dishonour unto learning to descend to inquiry upon matters mechanical [for as we should say nowadays experimental] (Vol 3 p 332)

"All true and fruitful Natural Philosophy hath a double ascent or ladder ascending and descending according from experiments to the invention of causes and descending from causes to the invention of new experiments" (Vol 3 pp 351 352)

"Those experiments he not esteemed which have an immediate and present use but those principally which are of most universal consequence for instruction or other experiments (Vol 3 p 352). The use of History Mechanical [that is experimental] is of all others the most radical and fundamental towards natural philosophy (Vol 3 p 332)

Then there is a fine passage emphasizing the value of experiment, too long to quote in full, it begins

But here was their chief error they charged the deceit upon the senses which in my judgement are very sufficient to certify and report truth though not always immediately yet by comparison by the help of instrument (Vol 3 pp 338 339)

Nowadays it is recognized that those who spend their lives investigating nature should be paid. Bacon anticipated us, saying

There will hardly be any man proficience in the disclosure of Nature except there be some allowance for expenses about experiments and therefore as secretaries and spies of princes and states bring in bills for intelligence, so you must allow the spies and intelligencers of Nature to bring in their bills or else you shall be ill advertised (Vol 3 p 325)

The *Advancement* tells us that medicine "is a most noble art" its object being "to tune this curious harp of man's body and reduce it to harmony." The author pities the physician, for he is judged by the event, "which is ever but as it is taken for who can tell if a patient die or recover whether it be art or accident?" And therefore many times the impostor is prized and the man of virtue taxed. Nay we see the weakness and credulity of man is such, as they will often prefer a mountebank or a witch before a learned physician" (Vol 3 p 371). Consequently physicians say to themselves, "If it befall to me as befallth to the fools why should I labour to be more wise?" (Vol 3, p 372)

Bacon criticizes the doctors of the day quite fairly, he finds that comparative anatomy, physiology, and morbid anatomy are not studied as they should be, that no use is made of vivisection and that if "a man look into their precepts and ministrations he shall find them but uncertainties and every day devices without any settled providence or project" (Vol 3, p 377). His attitude to medicine is shown in the sentence, "There is one thing still remaining which is of more consequence than all the rest—namely a true and active Natural Philosophy for the science of Medicine to be built upon" (Vol 4, p 336), and his attitude to science may be summed up in two sentences. "And this is the very thing which I am prepping and labouring at with all my might,—to make

the mind of man by help of wit, a match for the nature of things when he uses some direction and order in experimenting, it is as if he were led by the hand" (Vol 4, pp 412, 413)

Surely, after these extracts, we must believe that Bacon's own physician, Harvey, was influenced by his patient's book, which was widely known, was published some years before Harvey began his researches, contains much about medicine, and preaches reform of method and the use of experiment, in both of which Harvey's strength lay. I do not like to think that he was so ill educated as not to have followed other learned people in reading the *Advancement* by the author of the already popular *Essays*, for Bacon's contemporary, Ben Jonson, in a review of the great English writers, says of him "he who hath filled up all numbers, and performed that, in our tongue may be compared or preferred either to insolent Greece or to mighty Rome," and in these days we have Abbott speaking of Bacon's unique mastery of the English language. If we remember that these words are said of a man writing at the time of Shakespeare and the Authorized Version, then we get a measure of Bacon's greatness as a writer.

Another work of Bacon's that must have been known to Harvey before he made his discovery is *De Sapientia Veterum*, issued in 1609, it was much appreciated, and was soon reprinted and translated. Its general trend is welcome to a man well disposed towards experiment, for the proper investigation of Nature is recommended in it.

### The "Novum Organum"

In 1620 a book was published which began thus "The Great Instauration Prooemium. Francis of Verulam reasoned thus with himself and judged it to be for the interest of the present and future generations that they should be made acquainted with his thoughts" (Vol 4, p 7). He tells us that the human intellect makes its own difficulties and hence ignorance and mischiefs innumerable. Therefore the author is "to commence a total reconstruction of sciences, arts and all human knowledge" (Vol 4, p 8). Lest he should die before the work is finished, it was to be published in six parts. The first, which appeared after the second, was *De Inuentis*. The second, issued in 1620, was the *Novum Organum*, not quite completed. Only fragments of some of the other parts were ever written, Bacon calculated that his work when finished would be sixfold as voluminous as Pliny. If this estimate is correct we only have one-twentieth of the whole.

The *Novum Organum* has all the beauties of the *Advancement*, it is a masterpiece of condensed writing, without a word too many and each word precisely right. As with the *Advancement*, I will give extracts which will show that it also is just such a book as would help to form a mind like Harvey's. In the "Plan" introducing us to the *Novum Organum* we find this:

The subtlety of experiments is far greater than that of the sense itself. I contrive that the office of the sense shall be only to judge of the experiment and that the experiment shall judge of the thing" (Vol 4 p 26)

Those however who aspire not to guess and divine, but to discover and know who propose not to devise and mimic fabulous worlds of their own, but to examine and dissect the nature of this very world itself must go to facts themselves for everything" (Vol 4, p 28)

In the preface is this eloquent exhortation:

But if any man there be who aspires to penetrate further to overcome not an adversary in argument but nature in action, to seek, not petty and probable conjectures but certain and demonstrable knowledge with me that pressing by the outer courts of nature which numbers have trodden, we may find a way at length into her inner chambers" (Vol 4 p 42)

In the *Novum Organum* itself we are warned not to pin our faith to the syllogism, for the premisses being only words often there is no firmness in the superstructure—our only hope lies in a true induction. We are reminded that we can only progress by the study of particulars. We are told that "it is the peculiar and perpetual error of the human intellect to be more moved and excited by affirmatives than negatives, whereas it ought properly to hold itself indifferently disposed towards both alike" (Vol 4,

p 56) "What a man had rather were true he readily believes" (Vol 4, p 57) We suffer from "the mischievous authorities of systems, which are founded either on common notions or on a few experiments or on superstition" (Vol 4, p 66) Then follows advice to physicians to renounce all varieties of false reasoning for "the entrance into the kingdom of man, founded on the sciences, being not much other than the entrance into the kingdom of heaven, whereto none may enter except as a little child" (Vol 4, p 69) "The manner of making experiments which men now is blind and stupid" (Vol 4, p 70) "Men are inclined to turn aside from their experiments for some practical application of them, like Atalanta, they go aside to pick up the golden apple and let victory escape them they should seek for experiments of light, not for experiments of fruit" (Vol 4, p 71)

A few pages further on we find this beautiful passage:

"And an astonishing thing it is to one who rightly considers the matter, that no mortal should have seriously applied himself to the opening and laying out of a road for the human understanding direct from the sense, by a course of experiment orderly conducted and well built up, but that all has been left either to the rule of tradition, or the whirl and eddy of argument, or the fluctuation and mazes of chance and of vague and ill digested experience" (Vol 4, p 80)

"No one has yet been found so firm of mind and purpose as resolutely to compel himself to sweep away all theories and common notions and to apply the understanding thus made free and even, to a fresh examination of particulars" (Vol 4 p 81)

"A greater abundance of experiments is to be sought for and procured" (Vol 4, p 95)

Then to magnify the dignity of investigation Bacon quotes the proverb of Solomon, "The glory of God is to conceal a thing the glory of the king is to search it out" (Proverbs, 2)

Bound up with the first edition of the *Novum Organum* Bacon published a *Description of a Natural and Experimental History such as may serve for the foundation of a True Philosophy*. The introduction contains some of his most magnificent writing. Read this:

"Meanwhile what I have often said I must here emphatically repeat that if all the wits of all the ages had met or should hereafter meet together, if the whole human race had applied or shall hereafter apply themselves to Philosophy and the whole earth had been or shall be nothing but academies and colleges and schools of learned men, still without a natural and experimental history such as I am going to prescribe, no progress worthy of the human race could have been made or can be made in philosophy and the sciences. Whereas, on the other hand, if such a history be once provided and well set forth, and if there be added to it such auxiliary and light giving experiments as in the very course of interpretation will present themselves, as in this way, and in this way only, can the foundation of a true and active philosophy be established and then will men wake as from a deep sleep, and at once perceive what a difference there is between the dogmas and fictions of the old and a true and active philosophy and what it is in question of nature to consult nature herself" (Vol 4, p 252)

One more quotation from the same source I cannot resist "Away with antiquities and citations or the monies of authors" (Vol 4, p 254)

### Was Harvey indebted to the "Novum Organum"?

But, some may say, all this is beside the mark, for before this book appeared in 1620, Harvey, for at least four years, had been teaching that the blood circulates. Thus in a leading article in the *BRITISH MEDICAL JOURNAL* we find "a comparison of dates shows that Harvey could not owe anything to the *Novum Organum*". On the face of it this appears a fair inference, but it is probably incorrect because of the following considerations. The most trustworthy account we have of Bacon is that by his chaplain Rawle, who says:

"His book of the *Instauratio Magna* was the product of many years labour and travel. I myself have seen at least twelve copies of the *Instauratio* revised year by year, and another, and every year altered and amended in the first thereof, till at last it came to that model in which it was committed to the press. He would often ask if the meaning was expressed plainly enough."

Further, many tracts, which are trials for the future, were found among Bacon's papers after his death. Some were written as early as 1603 1605. I need not say

them as they can all be found in *The Works of Francis Bacon*. A quotation from the *Copitations* will suffice.

And it were shame that men should have examined so care-fully the tinklings of their own voice and should yet be so ignorant of the voice of nature. (Vol 5 p 425)

We see, therefore, that for many years before the publication of the *Novum Organum*, and before Harvey began his experiments, Bacon's mind was much occupied with it, and that he worked hard at it, making numerous trials. He certainly talked about it with his chaplain, consequently it is likely that he talked about it with his physician, of whom as we shall see presently, he probably saw much, for there was no secret about Bacon's philosophical work, he invited criticism from several friends, many had already read the *Idemneement* published earlier. He often spoke of his desire to study, and it was well known how he busied himself in his leisure. We can hardly err if we conclude that not only the thoughts expressed in the *Idemneement*, which we have seen Harvey had ample opportunity of reading before he began his experiments but also those which summered in Bacon's brain between the publication of this work and that of the *Novum Organum*, in which they were embodied were known to and affected Harvey, to whom they would have been particularly congenial, for he became one of the greatest of discoverers because he experimented and disregarded mere authority.

#### *Effect on Science of Bacon's Teaching*

If I have carried my readers with me so far, they are with me in thinking that Bacon's teaching touched the mind of Harvey. Yet it will be an advantage to see if this opinion is strengthened by what others have thought of the position of Bacon's writings in the history of science. Aristotle and Leonardo da Vinci had experimented, and several others such as Albert the Great, Vanini, Campanella, and Pamon Lull, as may be seen in Professor Peers's recent translation of *Blanquerna*,<sup>4</sup> saw that mere authority was allowed to override reason. Roger Bacon had laid down precepts that might have guided men aright but so abstract and dogmatic was the ordinary teaching up to the time of Francis Bacon that these examples bore little fruit being stifled under the mass of theological metaphysical and commentatorial literature with which the Middle Ages abounded. It was Francis Bacon who caused this deadening fog which bemused all originality to roll back when he directed men to discard authority and to seek out nature by proper observation, proper reasoning and proper experiment. People of his own time saw this. Rawley says "if there was a beam of knowledge derived from God upon any man in these modern times, it was upon him." Peter Heylin who was a young man when the *Great Instauration* was first published, tells us

The Lord Chancellor Bacon was a man of most strong Brain and a chymical Head. Pity it was he was not entertained with some liberal alary ab traeted from all Affairs both of Court and Jurisdiction and furnished with sufficiency both of Means and Help for the going on of his Design. Which had it been he might have given us such a body of Natural Philosophy and made it so subservient to the public good that neither Aristotle nor Theophrastus amongst the ancients nor Paracelsus or the rest of our latter chymists would have been considerable.<sup>5</sup>

#### *Sprat writes*

I shall only mention one Great Man who had the true Imagination of the whole extent of this Enterprize as it is now set on foot and that is the Lord Bacon. His Genius was searching and inimitable.<sup>6</sup>

The enterprize was the foundation of the Royal Society and it is generally allowed that it was Bacon's *New Atlantis* and the thoughts inspired in others by him which led to the foundation not only of the Royal Society but also of several foreign scientific associations. Metaphysical Fowler in his poem to this Society writes thus

Bacon like Moses led us forth at last  
The barren Wilderness he past  
Did on the very Border stand  
Of the blest promisd Land  
And from the Mountain's top of his exalted V'it  
Saw it himself and shewed us it

So much for the past opinion of Bacon's influence. During three centuries it has remained unchanged. We

find Leibnitz' remarking "We do well to think highly of Verulam for his hard savings have a deep meaning in them." Whewell mentions no other author in his preface and begins his book with a quotation from Bacon, and Macaulay writes that Bacon "moved the intellects which moved the world." Space allows me to quote only two modern writers. Professor Fowler<sup>10</sup> tells us "What Bacon says of Plato is preeminently true of himself, he was 'a man of a sublime genius who took a view of everything as from a high roel'." He popularized and dignified experimentation and the study of nature. "It would hardly, I think be an exaggeration to compare Bacon in the intellectual sphere with Luther in the sphere of religion." Church<sup>11</sup> writes that Bacon "had the brightest, richest largest mind but one, in the age which had seen Shakesperro and his fellows." Later on he says, "in temper, in honesty in labour in humility, in reverence he was the most perfect example that the world had yet seen of the student of nature, the enthusiast for knowledge." In the introduction to Fowler's edition of the *Novum Organum* will be found a long list of testimonies by many writers to the extraordinary power that Bacon's teaching has had upon scientific thought and production. The chief claim that Bacon made for himself is quaintly expressed in the letter he wrote to Dr Playfer "I have only taken upon me to ring a bell to call other wits together (which is the meanest office), it cannot but be consonant to my desire, to have the bell heard as far as can be." Truly its peal has been heard all over the world and has reverberated for three centuries, and surely these references suggest that Harvey must have heard its call.

#### *Bacon's Personality*

Having shown that Bacon's teaching was available to Harvey, as well known while he was a young man, and would be attractive to him, let us see whether the last is true also of Bacon's personality. Nobody is more likely to know him well than his secretary Meautys and his chaplain Rawley. Both were devoted to him and the first says his sole ambition is to grow up only under his Lordship and, come what come may to serve him with his life and fortune, laying down all he has at his feet.<sup>12</sup> The second shows us that Bacon must have been a delightful conversational companion.

His meals were reflections of the ear as well as of the stomach. "wherein a man might be refreshed in his mind and understanding no less than in his body." In which conversation he was no dashing man as some men are but ever a countenancer and fosterer of another man's parts. Neither was he one that would appropriate the speech wholly to himself or delight to critic others but leave a liberty to the conversators to take their turn.<sup>13</sup>

Tobias Mathew son of the Archbishop of York says of Bacon "It is not his greatness I admire but his virtue. It is not the favours I have received of him that have enthralled and encharmed my heart but his whole life and character which are such that if he were of an inferior condition, I could not honour him the less and if he were my enemy I should not the less love and endeavour to serve him."<sup>14</sup>

Ben Jonson tells lovingly of his virtue and thus of his speech

No man ever spake more neatly more pressly more weightily or suffered less emptiness less idleness in what he uttered. No man had their affections more in his power. The fear of every man that heard him was lest he should make an end.<sup>15</sup>

His secretary and apothecary, Boener, hoped that a statue of him would be put up not because of his learning, but on account of his being "a memorable example to all of virtue kindness peacefulness and patience."<sup>16</sup>

We know a man by his friends. Bacon drew them from everywhere. There were many abroad and in this country—Essex Buckingham, Lancelot Andrewes, Selden, Bodley, Hobbes, Jonson, Mathew and George Herbert the poet, who helped in the translation of the *Idemneement* into Latin and who wrote verses in praise of Bacon who in his turn dedicated his versification of the Psalms to Herbert saying he was his affectionate friend. Bacon had few enemies, the chief was Coke, his professional

antagonist. He was popular, as we learn from the fact that when he took his seat as Lord Keeper, besides the servants, the Judges, and the Inns of Court, he was accompanied by most of the nobility, with other gallants to the number of two hundred horse.

All this shows him to have been a lovable, charming person with whom everybody would enjoy talking, and it is incredible that his physician did not converse with him and that he was ignorant of his teaching.

#### Bacon's Health

On the whole, Bacon's health was good, nevertheless he was a chronic dyspeptic, giving considerable thought to his symptoms and indulging abundantly in remedies. He has left us very particular accounts of how he took these and how they acted.<sup>18</sup>

In 1617 he had an illness thought to be gout, but it only lasted a few days. A contemporary letter<sup>19</sup> says, "he hath so tender a constitution both of body and mind that he will hardly be able to undergo the burden of so much business." This surmise was incorrect, for during the next four years Bacon worked very hard. Two years later he was away from work for a time, probably owing to an attack of stone, "which held him in great pain two or three days."<sup>20</sup> That he was very fond of taking medicine is shown by these and other references, and by a letter written in 1623, which is of interest as having to do with the separation of the "Company of Potteryers" from that of Glocers, in it he says "You may perhaps think me partial to Potteryers, that have been ever puddering in physick all my life."<sup>21</sup>

Bacon depended on his physicians. When he was let out of the Tower he was not allowed to come within the verge of the Court, and thus he could not live in London. In some moods he thought the Tower preferable to such liberty, for he wrote in his petition to the House of Lords, "tho' I could have company, physicians," and he said the same in two letters to Buckingham, to whom, in a letter two years later, he again speaks of his physicians, whom he calls strange creatures. It is difficult to conceive a patient more likely to consult his physician frequently than one who was a chronic introspective dyspeptic, rejoiced in purgatives, had gout and a stone, especially as we have just seen that this patient was one with whom the physician would have delighted to talk, and many statements in *Sylva Sylvarum* suggest that Bacon often discoursed with doctors.

Further, apart from the relationship of patient and physician, Bacon and Harvey must have seen much of each other, for London was no bigger than a large provincial town of to-day, both moved among the Court and nobility, and both were in the small class of the well educated.

#### Harvey's Mind similar to Bacon's

I have now finished what may be called the Baconian side of my argument. The Harveyan side will be much shorter. The philosopher said observe and experiment properly, deduce scientifically, without attention to mere authority, no one could have done this more rigorously than the physician, whose mind was in this matter the counterpart of that of the philosopher, for Harvey said to Ent, "I have oftentimes wondered and even laughed at those who have fancied that everything had been so consummately and absolutely investigated by an Aristotle or a Galen or some other mighty name that nothing could by any possibility be added to their knowledge."—In the introduction to his work on the *Generation of Animals* he writes "Without the due admonition of the senses without frequent observation and reiterated experiment, our mind goes astray after phantoms and appearances." Further on "The method of investigating truth commonly pursued at this time therefore is to be held erroneous and almost foolish, in which so many inquire what others have said, and omit to ask whether the things themselves be actually so or not." Or, to take a passage from the introduction to *De Motu* "It will be proper to look more narrowly into the matter, to contemplate the motion of the heart and arteries, not only in man, but in all animals that have hearts, and further, by

frequent appeals to vivisection, and constant ocular inspection, to investigate and endeavour to find out truth."

Really, except that the language has not the mighty grandeur of that of Bacon, it might be his writing. So do the minds of Bacon and Harvey jump together that we are constrained to believe that the elder influenced the younger, particularly when we recollect the other reasons already given for this belief.

#### Value of Evidence that Harvey was not Influenced by Bacon

The view here put forward of the relationship between them is not that held by many writers, several of whom speak of Harvey's contempt for Bacon, or state that he can owe nothing to him. Those who maintain the latter have forgotten the *Advancement* and the history of the *Noëum Organum*. All who profess the first base it on the following Aubrey<sup>22</sup> tells us, "He [Harvey] had been physician to the Lord Chancellor Bacon, whom he esteemed much for his wit and style, but would not allow him to be a great philosopher. 'He writes philosophy like a Lord Chancellor,' said he to me, speaking in decision, 'I have cured him.'"

Assuredly this anecdote does not justify the belief that Harvey was not affected by Bacon. Aubrey tells us that it was not until 1651 that he became acquainted with Harvey, who was then 73 years old. Aubrey's statement is probably muddled, for, as Bacon had been dead twenty-five years, Harvey most likely said "he wrote," and for the same reason should have said "I cured him," and Aubrey does not make it clear whether Bacon was cured of a bodily ailment or of writing philosophy like a Lord Chancellor. Harvey, who according to Aubrey was very choleric and was certainly aged, was speaking of a patient dead twenty-five years before, and, being choleric, may easily, for mere argument's sake, have taken the other side to Aubrey in not allowing Bacon to be a great philosopher, and we must also remember that, even if this were Harvey's deliberate opinion, others have thought so too, but have, nevertheless, considered that Bacon did more than anyone to point the way to the proper mode of scientific research. We only have Aubrey's statement that Harvey spoke in decision of Bacon's way of writing, but, even if he did, we can only have meant that Bacon wrote in a stately, dignified, perhaps rather pontifical way, if he meant anything else he was very foolish, for, as already shown, it was allowed when Bacon was alive, and has been ever since, that few can match his prose. Certainly there is nothing in this story to suggest that Bacon did not influence Harvey, indeed, it is the other way, for he must have read the philosopher before he could give an opinion as to how he wrote, and we are told he esteemed his wisdom and style.

But quite apart from this argument there is another reason why we should not pay any attention to this anecdote—namely, that Aubrey is quite unreliable. He did not begin his *Lives* till 1680, when he put each name in a book then under it, when anything came into his head, he wrote hastily without reference to notes his recollections of the person, this was usually done in the morning, often in the midst of sickness following a night's drunk and debauch, and rarely revised. Harvey had been dead twenty-three years when this oft-quoted tale of that he said about Bacon, who had been dead fifty years, was jotted down in this manner by a gossiping drunkard who owns that he wrote "tumultuously." Look at it as we may, it is worthless as evidence as to what say Bacon had over Harvey. Indeed, Andrew Clark, Aubrey's editor, says "Aubrey's *Lives* supply an inviting field for comment, correction, and addition. But, even so treated, they will never be a biographical dictionary. Their value lies not in statement of biographical or other facts."

It has been implied that, because Harvey is so little mentioned by Bacon, we may infer that the two were far apart in record. In a notebook of Bacon's under the date of June 26th, 1608, he says he must ask for opinions about his scientific work from the physicians Poe, Padder, Hamond, but there is nothing to show that he ever did this. He would hardly have asked Harvey, for he was then only 30 years old, and probably was, at that time, un-  
known.

to Bacon: "I have looked through everything he wrote and it is clear that he was interested chiefly in physical science especially astronomy, but hardly at all in physiology. Many phrases having a physiological bearing are to be found in his writings, but they are all curious isolated statements if an explanation of them is given it is not Bacon—he merely reproduces the popular explanation. He collected hundreds of the statements for future investigation. Most we now know to be fantastic nonsense."

*De Motu* was published in 1628. Bacon died in 1626. Therefore he could not have alluded to the book. Harvey in his Lumleian Lectures began to teach his new doctrines not earlier than 1616 but there is no evidence that Bacon was ever present at these lectures. Indeed, from 1616 to 1620 he was at the very busiest part of his career, and he certainly had no time then to attend lectures nor to pay much attention to rumours which might come to him saying that a great discovery had been made especially as Harvey's experiments were then unconfirmed; indeed, if Bacon had asked doctors he would probably have been told that the new doctrines were nonsensical for we know that many of the medical profession did not think Harvey's views worthy of discussion. So far from it being surprising that there is nothing in the *Novum Organum* published in 1620, about Harvey's discovery which he began to teach, but only orally some four years before it would have been astonishing if there had been anything.

In *The History of Life and Death*, published in 1623, Bacon says, "the blood is that which irrigates the juices and membranes" and "the blood of the veins supplies the blood of the arteries." "It might be thought that these sentences show that he knew something of the circulation of the blood, but my strong opinion judging by the context is that he still knew nothing about it. Nor is this to be wondered at, for Bacon after his release from the Tower in 1621 lived a lonely life away from London and so would not hear of Harvey's lectures. To sum up the neglect of Bacon to mention Harvey is easily explained, and is of no value as indicating that the two were antipathetic."

It may be said that I have brought forward no direct proof of any influence of Bacon on Harvey. All my evidence is circumstantial. But two things are to be remembered: first, circumstantial evidence is often much stronger than direct; secondly, how little we know of the daily doings of people who lived three hundred years ago. Over and over again there is a reference in a letter to something Bacon had on hand but of the outcome of which we are completely ignorant. Speeding writes:

It is singular that of two men so remarkable in their several ways as Bacon and Coke whose fortunes objects tastes ideas and dispositions crossed each other at so many points and whose business must have brought them so continually into company and so frequently into conflict the personal relations should be so little known. No anecdote have been preserved by the news writers of the day which enable us to form a clear idea of their behaviour to each other when they met—the style of their conversation or the temper of their courtesies.

This being so it is not strange that we have no direct proof of Bacon's influence upon Harvey.

#### Gilbert's Influence

Everything goes to show that Harvey was regarded with affection by his own profession. He speaks of his "very dear friend Dr Argent" we know of Ent's tenderness for and admiration of him, of Prujean's esteem for him. His generosity to this College tells us that the Fellows of it were his friends whom he much loved but there is no indication that among these medical friends there was anyone of sufficient originality to help to mould Harvey's thoughts—with a single exception namely William Gilbert one of the great original geniuses among the famous Elizabethans.

He was born in 1540 at Colchester went to Cambridge took his M.D. there became a Fellow of St John's travelled abroad settled to practise in London in 1573, ultimately living in Wingfield House Peters Hill. Sylvanus Thompson's statement that his relations with English physicians were intimate and extensive must be correct for Gilbert held several offices at this College,

becoming President in 1600. He was well known outside his profession for he attended many celebrated people and was physician to Queen Elizabeth, the story that she left him a legacy shows her liking for him. Gilbert and Dr Lancelot Browne, in 1584, together signed a medical certificate which is preserved in the Records Office, in 1588 both were selected to advise the Privy Council about the health of the navy and Browne held various offices at the College of Physicians so in one way and another, he must have known Gilbert intimately. Lancelot Browne's daughter married Harvey in 1604. Gilbert died in 1605. Considering the close acquaintanceship between Gilbert and Browne Harvey must have heard much of the first and quite likely he met him when he was courting anyhow it appears that he knew a good deal about him, for Sylvanus Thompson tells us that according to Harvey, Gilbert expended no lesser sum than five thousand pounds on his researches. Therefore we may conclude that for both professional and family reasons Harvey would be inclined to pay attention to anything Gilbert said.

Gilbert's outstanding position is due to this. He broke away from tradition, he challenged authority, he went to Nature herself, investigating her by experiment, and he employed proper inductive reasoning. The first words in the preface of his famous book on the magnet are:

In the discovery of secret things and in the investigation of hidden causes stronger reasons are obtained from sure experiments and demonstrated arguments than from probable conjectures and the opinions of philosophical speculators of the common sort. But if any one be fit not to agree with the opinions here expressed and not to accept certain of my paradoxes still let them note the great multitude of experiments and discoveries—those it is chiefly that cause all philosophy to flourish and we have dug them up and demonstrated them with much pain and sleepless nights and great money expense."

This book made Gilbert the father of experimental philosophy in this island it is the earliest known work treating of both magnetism and electricity, few finer examples of inductive reasoning have ever been presented to the world, there is abundant testimony that it produced a deep impression not only in this country, but throughout the civilized universe it places Gilbert on a level with Harvey, Galileo, Grassendi and Descartes. Galileo says:

I extremely praise and admire and envy this author for that a conception so stupendous should come into his mind. I think him moreover worthy of extraordinary applause for the many new and true observations he has made."

Sir Kenelm Digby writes "by means of whom [Gilbert] and of Doctor Harvey our nation may claim even in this latter age as deserved a crown for solid philosophical learning."

Coming down to modern times C. W. Coole tells us that *De Magnete* inaugurated a new epoch in physical science its author announced discovery after discovery, all made by a series of experiments conducted in a most philosophical manner. He was the first electrician, he was the first to investigate electrical phenomena and the word 'electric' was coined by him. Sylvanus Thompson considers that Gilbert made twenty separate experimental discoveries in electricity alone.

It will not be amiss before we leave *De Magnete* to glance at the short reference to medicine to be found in it. In Book I Chapter xiv and xv Gilbert ridicules the medical nonsense which has been talked about the loadstone—such as that in small doses it preserves youth, that smeared with garlic it ceases to be active that when pulverized and then buried in a plaster it will draw an arrow from the body that it will cure all sorts of headaches. He sums up by saying "Thus vainly and preposterously do the schoolists look for remedies when ignorant of the true causes of things." Chapter xv treats of the medicinal virtue of iron. Gilbert is aware of its use in chlorosis for "it restores young girls when pallid sickly and lacking colour, to health and beauty." Malaria was very common in England in his time, hence we find Gilbert advising iron for enlarged spleen the patients improved probably because the iron benefited their anaemia. He notices that it is astringent. These are its only medicinal virtues. This is an excellent account

of the therapeutics of iron, we know but little more now. Gilbert is very sarcastic about the many ridiculous claims made for it by doctors. He says "Thus do the smatterers cross swords together, and puzzle inquiring minds by their vague conjectures, and wrangle for trifles as for goats' wool, when they philosophize wrongly." In Book II, Chapter III, he points out that Galen errs in believing that whatever agents draw out the venom of serpents exhibit the same power as the lodestone, he is emphatic that drugs do not act in this way. These extracts show him to have been what was very rare in his day—namely, a scientific physician, believing no more than he sees, and scornfully disbelieving the rubbish that passed for medicine.

*The Advancement of Learning* appeared in 1605, two years after Gilbert's death, so it cannot have been of use to him, and the only one of Bacon's writings which can have been published before 1600, when *De Magnete* appeared, is *Partus Masculus Temporis* (The Male Birth of Time), but the date of this, which is only a fragment, is doubtful. There is no trace of any acquaintance between Gilbert and Bacon; therefore we must admit that there is nothing to show that the last can have affected the elder, consequently the glory of being the first, in this country at any rate, to break through the bonds of authorities and properly to use experiments and induction belongs to Gilbert. Considering his professional position, his sound mediocrity, his close acquaintance with Harvey's father-in-law, the fact that his arresting book appeared just when Harvey was beginning his medical work, that it was just such as would appeal to the discoverer of the circulation (for it, by example and precept, taught that the right way to investigate nature was by experiment and induction), and that Harvey's recreation in mind all this, it is not that Gilbert helped to direct

Harvey's thoughts

#### *The Atmosphere in which Gilbert, Bacon, and Harvey lived*

Hitherto we have only considered Bacon, Gilbert, and Harvey individually, but in what atmosphere did they live? Sir John Edwin Sandys tells us that "the love of discussing on learned and philosophic topics was one of the characteristics of serious society in the Elizabethan age."<sup>36</sup> Sir Sidney Lee and Dr. Furnivall both say that the era of Elizabeth was that of learned culture and a desire for knowledge among large numbers of the people.<sup>37</sup> Several accounts have been given of the Society of Antiquaries, founded in 1572. It was a great success. "Peers and commoners, diplomatists and exchequer officials, heralds and city tradesmen, country and town gentlemen, schoolmasters, lawyers and clergymen, all met together, week by week to discuss archeological and constitutional problems."<sup>38</sup> At the same time there was another learned society which met at Gilbert's house on St. Peter's Hill. Sir Humphrey Gilbert, half-brother to Sir Walter Raleigh, had before Queen Elizabeth a scheme for the erection of "An Academy for education of her Maesties Widows and others, the youth of nobility and gentlemen." It was to have been a real University of London, there were to be dozens of well paid teachers, including one in natural philosophy, and there was to be one doctor of physic. His duties I will give in the old spelling. One day he was to read physic and another surgery, in the English tongue. He was never to allege any medicine of any kind, but that he was to declare the reason philosophical of every particular, and he was to show how the medicine was made and all the instruments used in making it. The physician was to practise surgery because there were very few good surgeons, for surgery was only to be learned in barbers' shops, which was most dangerous. The physician was continually to practise with the Natural Philosopher to try and search out the riddles of nature, they were to share a garden for the growing of simples, and for this they were to have an extra allowance.<sup>39</sup>

Learning was evidently much in men's thoughts and in their conversation. Therefore on this ground also we may reasonably conclude that Harvey would have knowledge of the teaching of Gilbert and Bacon.

Many who have written about the glorious Elizabethan renaissance have told us of its literature, its theatre, its politics, its statesmen, its voyagers, and its romances. A few have dwelt upon its science. Until the closing years of the great queen's reign ignorance, superstition, tradition and false reasoning darkened understanding, but that with other branches of human activity, so with science, great lights arose in this country—Gilbert, Bacon, Harvey, men's minds awoke, the science of electricity was founded, we were taught how to reason, and modern physiology was born. English science dates from the three who were contemporaries, fortunately they were not like Galileo, Bruno, and others, persecuted on account of the novelty of their pronouncements. The Elizabethan era is an example of the well known, singular phenomenon that there are no periods in which a cluster of geniuses appear, and this College can justly be proud that two of its fellows may be grouped with Shakespeare and a few others among the greater Elizabethans. Harvey's supreme eminence among scientists is so well acknowledged that there is no need for me to extol it. Rather have I tried to show that not only was he a star of the first magnitude himself, but he was also part of one of the brightest constellations the world has seen. No man can certainly say what makes any man's mind, but for the reasons brought forward in this article it does seem likely that, as Harvey was the youngest of these three, the other two had some directing effect, of which Harvey was perhaps unaware, in steering his thoughts correctly towards that goal the reaching of which has made him one of the great men of all time.

All three were pierced with a thirst for knowledge, and it would be difficult to find a better epilogue to this article than a quotation from the *Praise of Knowledge*, a poem written by Bacon and performed before Elizabeth in 1572.

"Therefore no doubt the sovereignty of man hath had in knowledge wherein many things are reserved which kings with their treasure cannot buy, nor with their force command it, and intelligencers can give no news of them, their sense and discoverers cannot sail where they grow. Now we govern men in opinions but are thrall to her in necessities. But if we be led by her in invention we should command her in action."

## THE TOBACCO HABIT

BEING THE NORMAN KERR LECTURE DELIVERED BEFORE THE SOCIETY FOR THE STUDY OF INEBRIETY,

BY

W. E. DIXON, M.D., F.R.S.

(FELLOW OF THE PHARMACEUTICAL LABORATORY, CAMBRIDGE)

NICOTINE, next to caffeine, is the alkaloid most widely used by man, and as in the last twenty years a truly enormous increase in the consumption of tobacco has occurred, it is right that a society like this, which concerns itself with every form of inebriety, should interest itself in the effects of smoking both on the health of the individual and of the population as a whole. Disraeli said "the youth of a nation are the trustees of posterity", and if the numbers of men rejected as unfit for military service in the late war form any criterion of the physical efficiency of our sons few can doubt that British stimulus leaves much to be desired if it is not indeed on the wane. I believe that no excuse is necessary for calling attention to certain known facts concerning tobacco smoking. The late Dr Norman Kerr, whose memorial lecture I have the honour to deliver to-day, wrote on some of the evils of tobacco, and especially its action in producing eye defects.

### HISTORICAL

Europe learned the use of tobacco from the American Indians. Tobacco is an Indian word, but nicotine is named after the French Ambassador in Lisbon, Jean Nicot. He grew tobacco seed in his garden and vainly tried the leaves as a cure for all external diseases. Snuff obtained from Nicot was introduced by Catherine de Medici at the French Court about 1560 as a specific for headaches.

Tobacco was brought into this country by Ralph Lane in 1585. He taught its use to Raleigh, who became a devotee, did much to popularize it, and carried his habit even to the scaffold. By the seventeenth century the use of tobacco had spread to almost every European country.

A reaction against its use arose in the fifteenth and sixteenth centuries. James I. published in 1603 a pamphlet entitled *Monopsonus seu de abusu Tabaci* in which he says:

*O cives si quis pudor rem insanam abiecte ortem ex ignominia receptam errore frequentem stultitia unde et ira numini accenditur dignitas gentis senescit domus videscit foris rem seu turpem olfactu insuavem cerebro noxam pulmonibus damnosam et si dicere liceat atrii fumi nebulis tartareos vapores proxime repræsentantem.*

The Tsar Michael punished his soldiers with the rack and knout for smoking; Urban VIII. forbade the use of tobacco in any form in church during divine service. How serious must have been the abuse of tobacco in Spain in 1642 may be judged from the apostolic brief which tells us that the priests chewed tobacco during service contaminated the vestments with expectoration and filled the church with fumes. Benedict XIII., himself a snuff-taker, rescinded the prohibition in 1724, but ordered that the use of tobacco in the Church of St. Peter at Rome should cause no disturbance, smoking was consequently excluded though I believe that the use of snuff is allowed in Catholic churches to-day. Nevertheless, neither the King's hook, the Czar's knout, nor the Pope's proclamation seriously affected the use of tobacco.

To the Puritans in England of the seventeenth century smoking was the mark of the drunken Cavalier. Nevertheless the Roundheads later indulged, since Evelyn states that the soldiers took tobacco at Cromwell's funeral. The association of smoking with the roisterer and drunkard prevented its acceptance in society till the end of the eighteenth century. During the Regency the meerschaum and cigar appeared in the streets, but in no clubs except the military. Cigarettes reached us from Spain. A Greek, John Theodoris, who settled in Leicester Square in 1851,

was the first to make them in this country, and, being more portable and easily concealed, they quickly invaded the home. Nevertheless, it was not really till post-Victorian days that the respectability of smoking was established. Women were the most bitter opponents of tobacco till this time with their emancipation about a third of the women started to smoke, and now it is even unusual for either a maid or matron to abstain.

The use of tobacco then, has become universal throughout the world. In this country no serious attempt has been made to determine its effect on the public health. America has been more active. Miss Luer Gaston, under the auspices of the Anti Cigarette League, has been instrumental in organizing several national congresses. The twentieth amendment to the Constitution of the United States of America, which has never been ratified provides that (1) The manufacture sale transportation, inhalation or otherwise consumption of cigars, cigarettes pipe tobacco cut plug and snuff is hereby prohibited. (2) The Congress and the several States shall have concurrent power to enforce this article by appropriate legislation, and to appoint enforcement officers in every community.

### COMPOSITION OF TOBACCO SMOKE

The smoke emitted from any smouldering vegetable matter, including tobacco, contains ammonia gas and pyridine or pyridine derivatives, and it is these substances which produce the irritation of mucous surfaces not infrequently observed in those who smoke. These bodies are responsible for the morning cough, the irritation of the throat and tongue and the conjunctivitis of the cigarette smoker. They are in every respect objectionable products and add nothing to the pleasure of smoking. If they could be excluded from the smoke it would be all to the benefit of the smoker. Other dried herbs—such, for example as coltsfoot leaves at one time sold as a boys' tobacco which was harmless—often produce more pyridine when allowed to smoulder than tobacco but they have none of its irritating effects.

The pyridine bases are oily volatile liquids, intensely irritant, but compared with nicotine, of a relatively low toxicity. Their poisonous nature I have demonstrated on young volunteers, who were required to smoke coltsfoot leaves after smoking for some time (twenty to thirty minutes) they suffered from nausea vomiting and diarrhoea, with all the signs of early shock. Nevertheless in tobacco smoking the only serious effect of these bodies is the local irritation since their specific effects are insignificant in comparison with those of other substances which are present in this smoke.

### CARBONIC OXIDE

Another substance obtained from the slow combustion of almost any vegetable matter including tobacco, is carbon monoxide which is also the poison of coal-gas and the exhaust gas from motor cars.

In New York and Newhaven where the motor traffic is dense CO can be detected in the air of the streets. The traffic control men not infrequently suffer from headache, slight nausea muscular weakness and rapid pulse which are the usual symptoms of CO poisoning. Wilson and others<sup>1</sup> examined the blood of fourteen foot traffic patrol men and found that it contained from 0 to 30 per cent of CO whilst six of these men showed values of from 20 to 30 per cent. Two other symptoms which are also prevalent are dizziness and more rarely dimness of vision.

The United States Bureau of Mines made experiments to determine the CO present in a confined space after intensive smoking and found that the CO concentration of the air of the room did not rise to more than 0.01 per cent and the maximum blood saturation of the subjects exposed to this atmosphere was only 5 per cent. Nevertheless this is more than enough seriously to affect sensitive people. When the amount of this gas is determined in the smoke of cigars, cigarettes and pipes under conditions simulating as far as possible those obtaining during ordinary smoking the figures obtained are somewhat alarming. The cigarette smoke yields from 0.5 to 1 per cent the pipe 1 per cent or more and the cigar 5 to 8 per cent, this last, as

Professor Armstrong points out, is roughly the proportion of CO in the coal-gas of the South Metropolitan Company. The amount of CO varies naturally with the rapidity of the smoking and the closeness of the packing—the quicker the smoking the more CO.

Tobacco smoke, however, reaches the mouth freely diluted with air, and the amount of CO absorbed from the buccal cavity is negligible, so that pipe and cigar smokers who do not inhale have little to fear from this poison. Cigarette smokers who inhale would absorb a large proportion of the CO which reaches the lungs, since the affinity of CO for blood is more than two hundred times that of oxygen. Cigarette smoke as it reaches the mouth of the smoker may contain as much as 72 to 25 parts of CO in 10,000 parts of air (Baumberger). Inhaled for one hour at the rate of five puffs a minute this should be enough to affect appreciably the blood haemoglobin. Many years ago Fokker asserted that animals placed in an atmosphere containing tobacco smoke died from CO poisoning. Hartidge<sup>7</sup> found 6 per cent CO in the blood in one cigarette smoker who was by no means excessive in his habits. The normal healthy man does not in most cases show symptoms of CO poisoning until 15 to 20 per cent of his haemoglobin has been fixed and put out of action. Yet there are many people who show a supersensitiveness to this poison, just as some of us have some idiosyncrasy for quinine or iodides, and so it is not difficult to appreciate why cigarette smokers may exhibit a syndrome indistinguishable from that of mild CO poisoning.

The toxic concentration of CO in the atmosphere is about 0.05 per cent, in men exposed to dilute concentration, such as 0.02 per cent, the degree of haemoglobin saturation would be perhaps somewhere near 20 per cent.<sup>7a</sup>

#### NICOTINE

The third and by far the most important constituent of tobacco is the volatile alkaloid nicotine. The effects of cigar and pipe smoking are due practically entirely to nicotine, which exists in tobacco combined with organic acids. During smoking these salts are largely dissociated, a part of the nicotine being burnt and a part passing in the smoke as free nicotine. The drier the tobacco the greater the destruction of the nicotine. Moist tobacco produces much more serious effects than dry tobacco, and it has been stated that the moistness of the tobacco is responsible for many of the evils. The water content of the tobacco is much more harmful to the smoker than the original nicotine content of the tobacco.

During the slow combustion of a cigar as in ordinary smoking there is an area immediately behind the point of combustion in which the water and other volatile substances condense. During aspiration the hot gases are drawn through this hot moist area and carry with them the volatile principles, of which nicotine is the most important. Hence the smaller this moist area behind the point of combustion—which means, the cooler the smoke or the more complete the combustion—the less likely is the smoke to contain volatile toxic bodies. It follows that a cigarette or slender cigar which is well cooled will yield fewer of these products than a thick cigar, and many smokers can testify that a fat cigar has a much greater effect than a long slender cigar of similar tobacco. This also explains the unpleasant effects of relighting a half-finished cigar or pipe.

The same principle is exemplified by the following fact. Virginian tobacco leaf from which cigarettes are made often contains double the amount of nicotine that is present in Manila cigars. Yet when an equal weight of the cigarettes and cigars is smoked the total cigar smoke contains double the amount of nicotine present in the cigarette smoke. The condition of the tobacco and the form in which it is smoked are more important factors in determining the amount of nicotine in the smoke than the amount of nicotine present in the original tobacco.

The species of plant mostly used is *N. tabacum*, but several other species are employed, thus *N. rustica* yields Turkish tobacco, different varieties of tobacco from the same species also show different amounts of nicotine. During the process of curing the leaves, which consists

in exposing them under cover to a considerable degree of heat, important chemical changes occur, the leaves become moist and their fragrance alters. There is much reason here for further investigations, with a view to producing a tobacco which when smoked would yield in the smoke the minimum of alkaloids, pyridine, etc., whilst retaining its aroma. Tobacco may contain anything from 1 to 8 per cent of nicotine, Havana tobacco has about 1.5 per cent, Maryland 2 per cent, Virginia 6 per cent, Kentucky 8 per cent.

#### AMOUNT OF NICOTINE IN SMOKE

The amount of nicotine in tobacco is no criterion of the amount in its smoke. For example, mild honeydew contains only 1.6 per cent, whilst Cavendish may contain as much as 3.8 per cent, if these two are smoked under identical conditions the Cavendish naturally yields the larger amount of nicotine in the smoke. But Cavendish smoked in a cool pipe or one provided with a filter will affect the smoker less than the honeydew smoked in a hot pipe. In the churchwarden pipe the opportunity for the nicotine to condense is such that the smoke is almost freed from the alkaloid, and I have already pointed out that in cigar and cigarette smoking the degree of moisture, the tightness of packing, and the thickness of the cigar or cigarette are the most important factors in determining the amount of nicotine which will be present in the smoke. Harbermann<sup>8</sup> and Eichenfeld<sup>9</sup> state that two-thirds of the nicotine of some kinds of cigars passes over in the smoke, with other brands as little as one twenty-fourth passes over.

Lehmann<sup>9</sup> obtained nicotine from the air of a room in which tobacco was being consumed, showing that the smoke is by no means denuded of all its alkaloid. He thinks from his calculations that only about 1.4 mg nicotine is absorbed from a cigar. This figure depends on so many conditions that it cannot be accepted—for example, the length of time that the smoke is held in the mouth, the affording time for absorption, would exert an enormous influence. Our own observations suggest that the figure is ten times too small. The collapse which I have seen in youths smoking a Manila cigar could not have been produced by the absorption of such an amount.

Ashorton (1919) says that 6 to 8 mg of nicotine reach the mouth from a cigarette smoked in the usual way. We are not told, however, how much of this is likely to be absorbed. In our own observations, using a standard Virginia cigarette weighing 1 gram and aspirating the smoke through solvents once in twelve seconds, and using only three-fourths of the cigarette, it was found that 3 mg of nicotine were absorbed. It must not be assumed that this is necessarily absorbed into the system, but in the case of an inhaler most of it certainly is, perhaps 75 per cent, since expectoration is no longer permitted and loss occurs through the exhaled smoke only. Hence if a cigarette smoker were to puff ten cigarettes on end he would certainly absorb 20 to 30 mg of nicotine—enough to produce a profound physiological effect, though, administered in this way, perhaps ten to fifteen times under the lethal dose. The amount of nicotine in pipe and cigar smoking is much higher. In our experiments cigar smoke contains about twice as much nicotine as cigarette smoke.

Other constituents of tobacco smoke are less important. The solids of cigarette smoke weigh about 10 per cent of the tobacco burned—that is, 80 mg for each cigar. Cyanides and sulphocyanides are present in trace, and is a constituent of American tobaccos in amount 10 times greater than those permitted in foods. Pipe tobacco is reported to contain the equivalent of from 0.6 to 0.27 grains As<sub>2</sub>O<sub>3</sub> per lb.<sup>10</sup> When smoked probably half this will be absorbed.

These facts show that nicotine is a most important constituent of tobacco. It is one of the most fatal and rapid poisons known, it acts as quickly as prussic acid and two drops placed on the tongue of a dog will kill it almost immediately. The lethal dose for a man is 120 mg. The nicotine present in one cigar if injected intravenously would represent two fatal doses to man. It is therefore somewhat remarkable that fatal nicotine poisoning is not more common. Nevertheless the careless

tobacco infusions in enemas, the occasional swallowing of tobacco leaves, or even carrying tobacco leaves next to the skin for smuggling purposes, have all led to fatal results.<sup>11</sup> Tobacco has also been used for criminal purposes,<sup>12</sup> but as it does not appear to undergo fermentative changes in the cadaver it can be detected in the bodies of animals three months after death.

#### DENICOTINIZED TOBACCO

If tobacco is heated at a temperature over 100° it gives off an empyreumatic oil which was official in the *L. S. Pharmacopoeia* of 1870 as *oleum tabaci*. This oil is rich in nicotine, has an odour resembling foul pipes and is extremely toxic. Various methods have been adopted to eliminate the nicotine from the smoke and the juice which is apt to form in pipes. A porous substance may be put into the stem of the pipe, the space for cooling and condensation may be increased, or some substance which facilitates oxidation may be placed in the bowl of the pipe. These last pipes are called catalytic and the bowls are lined with some metallic oxide, like that of platinum in a fine state of division. By passing tobacco smoke over the catalyser formol is formed and the nicotine and pyridine derivatives are decomposed. The c pipes have not, however, found favour.

Another method of improving tobacco consists in removing some of its nicotine by means of solvents. These so-called denicotinized tobaccos have 50 per cent. or more of their nicotine removed, and have been regarded therefore by physicians as relatively harmless at all events as far as their nicotine is concerned.<sup>13</sup> Unfortunately this is not the case because it has been shown that these denicotinized cigars yield in their smoke as much nicotine as was present in the same class of cigar before denicotinization.<sup>14</sup>

Improved methods of removing the nicotine are however now being experimented with abroad. Boxes or cigarettes and tobaccos in various forms are treated with superheated steam by this means practically the whole of the nicotine is said to be removed and the tobacco is left nicotine free. The nicotine has a ready sale for agricultural purposes. I have had no opportunity, however, of experimenting with these products.

It will be obvious from this that great opportunities exist for investigating and improving tobaccos. Tobacco is a substance foreign to the body and its alkaloid is poisonous, the user pays heavily for his vice in raves, and it is entirely not unreasonable that he should have some further guarantee of the quality of the material which he buys than that provided by the 1842 Act. I am not suggesting that tobacco should be guaranteed to contain not more than a specified amount of nicotine in the same way as spirits are standardized for alcohol, but as tobacco is similar to alcoholic beverages in that excess of both leads to serious result the public should have some sort of guidance or protection. It is almost certain, for example that it is the nicotiness of the tobacco which is indirectly responsible for many of its most serious effects: that the pyridine derivatives are largely responsible for morning cough which leads later to chronic bronchitis and cardiac failure. These are conditions which at least are capable of improvement. The Minister of Health which has already done much for providing pure foods of a certain standard, will, I hope, not long see in tobacco an important factor in the public health.

#### ACTION OF TOBACCO SMOKE

Tobacco used in any form possesses irritant properties, this is of course obvious with snuff, the use of which depends on stimulation of the fifth nerve endings. The same action occurs in chewing which excites reflex salivation. If five or six grains of tobacco are swallowed vomiting occurs. Tobacco is irritating also to the skin, and the alkaloid in it is readily absorbed. Many cases of poisoning are on record, and I have in mind particularly a child of 8 years suffering from *tinca capitis* to whose head the expressed juice of tobacco leaves was applied, the treatment was shortly followed by death. Several cases of tobacco poisoning through the skin are reported in the *British Medical Journal* for 1926. Carlin in 1913

described the case of a girl aged 6 years who died forty five minutes after receiving an enema of 24 grains of tobacco. From an examination of such cases it is clear that death may occur from three minutes to several hours after using tobacco as an enema or for application to the skin.

Continuous smoking for several years not infrequently produces signs of chronic irritation in the month, throat, and larynx—sore tongue, morning cough, hoarseness, tonsillitis or chronic bronchitis. I believe that these effects are most marked in the cigarette inhaler. When the smoke is concentrated on one portion of the tongue for many years, which may occur especially in pipe smoking this constant irritation is said to favour the formation of epithelioma of the lip and tongue if the quantity consumed is large or the smoker predisposed.<sup>15</sup> The evidence in support of nicotine taking any part in this action is certainly not conclusive. Nevertheless, Bottini mentions one hundred cases of cancer which he saw including three women, which were caused by smoking or chewing tobacco. On the other hand, the Registrar General's report shows a remarkable fact to which attention has not been drawn previously—that tobacco manufacturers have a lower death rate from cancer than those of any other trade.

Smoking is reputed amongst the public to have an antiseptic action, and is sometimes indulged in nominally for this purpose. Pepys describes the use of tobacco during the plague, and its use was compulsory at London in 1721 as a prophylactic against 'the apprehension'.<sup>16</sup> Pantoni<sup>17</sup> and others have shown that tobacco smoke has a strong disinfectant action *in vitro*. When the smoke is drawn into the month however, the action is attenuated by the saliva and mucus, and its antiseptic effect is negligible. The action *in vitro* is not influenced by filtering the smoke free from nicotine by passing it through cotton wool.

#### SPECIFIC ACTION

Smoking is, however, indulged in by man because of its sedative action and this is due solely to nicotine absorption. Nicotine stimulates all nerve cells throughout the body without exerting any kind of selective action and the stimulation is followed by depression. The time the stimulation lasts depends on various factors but as a rule it coincides with the absorption of the nicotine—that is, with the period of active smoking. Both the pleasures and evils of smoking are intimately connected with nicotine. Morphine, heroin, cocaine and other drugs of addiction have a selective action on the central nervous system alone nicotine is different: it acts also on the autonomic nervous system, and it is this action which produces objectionable effects in the sensitive or excessive smoker.

#### ALIMENTARY CANAL

The commonest symptoms of smoking are loss of appetite and chronic intestinal catarrh. The smoker's lack of appetite Sir Humphry Rolleston thinks is not altogether an evil, since it limits the consumption of unneeded articles. Nicotine and tobacco smoking by stimulating the autonomic ganglia, increase the secretion of the alimentary glands, and later, after the smoking has ceased depress them: hence the salivation during smoking and the dry mouth the following day. The same fact is true of gastric secretion. Experiments have been made on dogs with a Heidenhain's fistula by means of which the secretion of gastric juice may be collected and examined as desired. Injections into these animals of nicotine or saline solution through which smoke has been passed afford a means of determining accurately the effect on gastric secretion. Both affect the dog in the same way, and cause at first a decided increase in gastric secretion.<sup>18</sup> It is well recognized that in certain persons excessive smoking leads to this gastric hypersecretion, hyperacidity is the most common disturbance and gastritis acid is one of the most frequent results. Hurst<sup>19</sup> believes that tobacco smoking is one of the most frequent causes of hyperchlorhydria. Rolleston<sup>20</sup> lays considerable stress on the relative sensitiveness of the individual as an important factor in determining whether or not a heavy smoker will pay the penalty of gastric disease.

On the musculature of the alimentary canal the action

of tobacco is equally well marked, the automatic movements are first inhibited and later augmented, as a result of stimulation and later depression of the autonomic nervous system.<sup>19</sup> The inhibitory stage is almost coincident with the period of smoking, and is associated with contraction of the pyloric and ileocolic valves. Stimulation of the sympathetic nerves causes inhibition of the whole alimentary canal with the exception of these two valves, which are contracted. The dyspepsia often following on a hypodermic injection of morphine is probably due to this pyloric contraction, which delays the passage of food. Morphine in this respect shows some similarity to nicotine. The mild laxative action of tobacco smoke may be explained by the ultimate depression of the inhibitory cells whereby the motor nerves assume an undue influence on the automatic movements.

Hunger is due to certain well recognized automatic contractions of the stomach, smoking definitely inhibits these. Hence continuous smoking stifles off the pangs of hunger, and acts in this respect like the drugs of addiction—cocaine and morphine. Careful experiments which have been made on habitual smokers and non-smokers with the aid of bismuth and x-rays show that the effect of smoking a cigar is to stop the normal automatic movements of the stomach within fifteen minutes. The inhibition continues until about three minutes after smoking has ceased, when the contractions begin again.<sup>20</sup> In these experiments it was also shown that nausea and vomiting from excessive absorption of nicotine may occur at a time when the stomach movements are completely inhibited.

Tobacco smoking, then, has a very definite action on the alimentary canal. In certain sensitive people it produces effects which, according to Huist, from the production of duodenal ulcer, whilst Wagner<sup>21</sup> insists that excessive smoking can produce all the subjective and x-ray appearances of this condition.

#### CIRCULATION

The considerable use of tobacco in any form invariably produces certain definite effects on the circulation which cause no inconvenience of any kind to the subject, these should be distinguished from other effects which only occasionally occur, but are then often sufficiently distressing to induce the sufferer to seek medical advice.

Under the first group must be included changes in the pulse rate. All observers are agreed that the use of tobacco increases the pulse rate from five to ten beats a minute, and in the case of the man who is continually smoking the increase of rate becomes permanent, but this condition produces no apparent disadvantage.

When the novice or moderate smoker puffs a cigar the rate of the pulse increases in a few minutes. Lee,<sup>22</sup> working in my laboratory, demonstrated this clearly both in the novice and moderate smoker under strict experimental conditions. In another series of experiments twenty-eight young healthy smokers were required to smoke a single Turkish cigarette, the pulse rate increased in all but four, and sixteen showed an increase of more than eight beats a minute.<sup>23</sup> Hesse<sup>24</sup> obtained similar results with cigars on twenty-five patients suffering from various chronic diseases.

During the war it was generally asserted that excessive smoking, particularly of cigarettes, was the common cause of the so-called D.A.H. Observations were made which showed that the average pulse rate of the patients during smoking was nine beats a minute higher than before smoking, in ten healthy controls it was six higher.<sup>25</sup> As there can be no question that the effect is due to nicotine, inhalers of cigarette smoke should show more acceleration than non-inhalers. In Paulson's twenty patients the ten inhalers showed an average increase of pulse rate of eleven a minute and the ten non-inhalers of seven.

This increase in the pulse rate is associated with a small rise in blood pressure for the moderate smoker the rise does not usually exceed 20 mm of Hg systolic, and 8 mm of Hg diastolic, and is usually even less. The rise begins a few minutes after the smoking has commenced and is maintained throughout the smoking period.<sup>26</sup> It is only in the case of the novice or after excessive smoking that

the blood pressure falls, to any extent below normal after the smoking has ceased, but under certain conditions the fall may be so severe as to cause all the signs and symptoms of shock or collapse.<sup>27</sup>

Observations have also been made to determine the effect of smoking continued over a period of six months. Nicolai and Strehlein smoked six or eight cigars a day for six months. They then gave up smoking, except for an occasional cigar, for a further six months. Their average pulse rate was 74.5, compared with 81.8 during the smoking period.<sup>28</sup>

These changes from the normal are, after all, usually small and give rise to no symptoms, but the evidence available suggests that they cannot be regarded with indifference. It is a maxim with those who are in training for athletic events that smoking must be entirely eschewed. This prohibition, no doubt adopted in the first place as the result of experience, has become a tradition. In Nicolai's experiments the acceleration of the pulse which occurred after the performance of a measured amount of work with the ergograph was considerably greater during the smoking period, while recovery to the normal rate was much slower than during the period of abstinence. Paulson and Koefod also showed that smoking a few cigarettes can render healthy men more breathless on exertion, and that this effect was marked in soldiers suffering from D.A.H. This means that the heart even of the moderate smoker is less efficient in periods of strain. It is possible, then, that the prohibition of smoking for athletes is dependent on this vascular effect. With present knowledge it would be mere speculation to attempt to gauge the significance of this factor when continued over many years.

#### MORE SERIOUS CIRCULATORY EFFECTS

Of the more definite effects which cause patients to seek advice are palpitation and arrhythmia, which are relatively common in the young, they disappear if the smoking is stopped, though in pronounced cases, as the late Sir Clifford Allbutt pointed out, only after the abstinence has been continued for many months. The arrhythmia is functional and is usually due to extra-systolic beats. Neuhof mentions fibrillation and flutter and sino-auricular block also, the block in the case he illustrated disappeared three days after smoking ceased,<sup>29</sup> but such cases must be very rare. Rolleston says that arrhythmia may occur at any age but is more noticeable after 50, this may be due to a loss of tolerance which is known to occur in later life.

Another symptom which may arise from excessive smoking in later life is anginal pain, which, according to Osler, much approximates to true angina. Taine says that it is associated with vasomotor disturbances and tends to occur after meals or in the night rather than after exertion.

Arterio-sclerosis is easily produced in animals, especially rabbits, by the injection of nicotine, and we have ourselves produced marked arterial changes in the aorta and larger arteries of animals by administering to them "smoke water", but I do not think that these experiments are proofs that smoking leads to arterio-sclerosis in man, although there is a consensus of clinical opinion that immoderate smoking favours arterio-sclerosis. Pawlowski<sup>30</sup> states that 42 per cent of 1,000 cases of coronary sclerosis had histories of immoderate smoking.

In severe cases the evidence irregularities may lead to syncope, and an undue proportion of sudden deaths during the middle period of life, without any definite lesion found *post mortem*, is said to occur in heavy smokers.<sup>31</sup> As even the most moderate smoking, places some disability on the heart, trifling though it be, it may well be that this view deserves serious consideration.

#### CENTRAL NERVOUS SYSTEM

Nicotine is essentially a nerve poison, but so far consideration has only been given to its action on the cells on the course of the autonomic system, and this action is responsible for the digestive and circulatory effects. But nicotine affects the brain and cord also. It increases spinal reflexes and removes certain inhibitions. I have already drawn attention to some of the effects

or excessive cigarette smoking in the young the attacks of giddiness, and the tremors. A large experience of examination papers of medical students enables me to pick out with certainty the heavy cigarette smokers from the irregular character of their writing. If the habit is broken the writing at once improves and the vertigo disappears. The effects are exactly those of CO poisoning and I believe can be explained on this basis.

Habitual smokers are agreed that the weed acts as a mild sedative to the central nervous system the type of action is of a somewhat remarkable character and may offer in explanation of the widespread use of tobacco. Physical fitness or well being is determined by our feelings which are the result of sensations. If response to sensation varies from the normal, whether on the hypo or hyper side it causes a return towards the normal and smoking is said to exert a similar effect though of a more marked description, hence the sedative effect of tobacco in conditions of irritation and the stimulating effect in the case of nervousness and depression. The experiments from which these statements were deduced consisted in determining the threshold to single brief induction shocks of two fingers immersed in saline solution. After this figure was determined the subject smoked two cigarettes and his threshold was re-examined. If the initial threshold was low smoking depressed it on an average 72 per cent. On the other hand if the initial threshold was high, smoking lowered it on an average 28 per cent. Suitable controls were made with cubb cigarettes which always acted as a stimulant. This shows also that the tobacco action is due to nicotine.<sup>20</sup> In the same way smoking tends to nullify the slight sensory depression produced by the veronal, antipyrine and other hypnotics.<sup>21</sup> So that it may well be that tobacco is helpful when the sensory threshold is abnormal.

#### MENTAL EFFICIENCY

Mental efficiency tests on the whole have not been very convincing. In Berry's experiments<sup>22</sup> smoking enabled his subjects to do more rapid and correct arithmetical addition but the nicotine here was not the determining factor, the aroma and holding an unlighted cigar or chewing substances like gum all had some effect. Turner lays much stress on the importance of these facts. Carver's experiments consisted in applying eight established psychological tests in a number of people to determine whether cigars or cigarettes would influence their judgement and response to stimuli. The results suggest that smoking lowers the accuracy of finely co-ordinated reactions and association-thought processes. The speed of complicated reactions was however unchanged. The habitual smoker, when deprived of his smoke for some hours, showed diminished accuracy.<sup>23</sup>

Many observations have been made by merely comparing the efficiency mental or physical of smokers and non smokers. All these experiments seem to me so difficult to interpret that their value is negligible. Generally they show some inferiority of the smokers. This is true of observations of scholarship<sup>24</sup> endurance of telegraph workers<sup>25</sup> scholarship and physical efficiency<sup>26</sup> and resistance to tuberculosis. The apparent inferiority may be the cause or the effect of the tobacco habit. Those who are handicapped by neurosis or other form of inferiority would succumb most easily to the euphoria of smoking.

The action of smoking on the performance of routine muscular work has also been examined, and it has been found that habitual smoking has no obvious effect on the output of work amongst glass-blowers, a moderately strenuous physical occupation, although chewing greatly diminished the output.<sup>27</sup> On the other hand, Lombard's experiments show that smoking diminishes muscular endurance both at the age of 35 and 60.<sup>28</sup> Using the ergograph, Palmán found that cigarette smoking at first increased muscular work, but that fatigue set in earlier and the total work was less. A curious periodicity occurs in the ergograph records after smoking due to fatigue or depression of the central nervous system.<sup>29</sup>

It must be conceded that ordinary smoking in normal people does not lead to nervous disturbances. Excessive

smoking is another matter, and may produce nervousness and insomnia. Every smoker knows that a stronger cigar than usual may keep him awake though usually the effects of smoking are soothing and favour sleep. Neurasthenic subjects are easily affected by smoking they are continually breaking off their smoking and returning to it again in a few weeks. They suffer from headaches, dizziness, and sudden sharp attacks of pain in the head, over the pre-cardial region, or in the stomach which cease when the smoking is stopped.<sup>30</sup> Neuralgias generally stated to be localized about the intercostal, humeral and scapular region are rare but of importance, as the pain continues until the cause is removed.

The action of tobacco then on the central nervous system, when used in moderation, on the whole does no harm, and in subjects showing deviations from the normal it makes for good.

#### AMBLYOPIA

Tobacco amblyopia stands alone in my chief so grave. It was noticed by Mackenzie in 1835 and observed accurately by Hutchinson in 1864. The sight gradually becomes dim with central scotoma, some derangement of accommodation, and often dilatation of the pupil. This condition is associated with retinobulbar optic neuritis and recovers if smoking is stopped when degeneration has set in however abstaining from nicotine will only arrest further progress.<sup>31</sup>

At one time those engaged in the manufacture of tobacco, in consequence of the absorption of powder, suffered from visual troubles. Dr Norman Kerr stated. In 3000 workers in a tobacco factory 150 had eye defects, 45 being seriously affected. Galzowski, de Selverwitz and many others have verified the facts. Nevertheless with improved sanitary arrangements the effects have now disappeared.

Androgné, in a critical analysis of 48 cases of amblyopia from axial neuritis due to nicotine saw the quality of the tobacco as at fault it was imperfectly dried which means that the percentage of nicotine in the smoke is much greater than usual.<sup>32</sup>

#### TOLERANCE

The rapidity with which people become accustomed to nicotine is well known, but is none the less remarkable. The degree of tolerance varies in different people, but it is never absolute. Wahl in 1920 found that non smokers suffered from nausea and vomiting after taking by the mouth 1 to 2 mg. of nicotine. On the other hand, smokers required more than 8 mg. to produce the same effect.

Various methods are known by which tolerance to drugs may be attained. Habitual dosing with a drug is sometimes met by diminished absorption, or the drug may combine with some substance which renders it non toxic. Salicylic acid is rendered inactive by combining with glycocoll, though whether it is possible to attain a tolerance by this means is not known. Tolerance can also be attained by destruction of the toxic agent. Hence alcohol affords an example for whilst it is true that all mammals can oxidize this body the rate of oxidation may be increased by habit. This method of obtaining tolerance by destruction applies to alkaloids also, as was shown by Faust<sup>33</sup> for morphine and Cloetta<sup>34</sup> for atropine.

Many investigators claim that tolerance to nicotine cannot be produced in animals but the methods employed were not of the kind which would show small degrees of tolerance. All the experiments however, show that whatever the condition of the animal as regards tolerance if nicotine can reach the tissue upon which it acts—that is nerve cells—it produces its normal effect. This leaves only two probable explanations of the tolerance in man. The first is that nicotine is not absorbed in the tolerant man. Clinical evidence rebuts this supposition it is well recognized that excessive smoking may produce toxic effects—alimentary cardiac and nervous—even in the most inveterate smokers. The second explanation is that the nicotine is destroyed as an active substance, but that the rate of destruction is limited.<sup>35</sup> If the destruction were carried out only slowly by the tissues like the oxidation of alcohol and sugar, that would not necessarily prevent the nicotine exerting a physiological action, and if the rate of absorption exceeded that of destruction, a nicotine

action would certainly be obtained. When nicotine is introduced directly into the circulation the destruction within a few seconds would be negligible, and so the whole of the specific action would be obtained, no matter what the degree of tolerance.

The experiments of Lee and myself<sup>16</sup> were made on rabbits, and showed that repeated injections of nicotine into an animal give to the tissues, and especially the liver, an increased power of destroying the toxicity of the nicotine. It is easy to conceive of several ways in which this might be brought about, but some of these possibilities may be eliminated by experiment.

The loss of activity proceeds very slowly, this might be anticipated, for if it occurred rapidly a high degree of tolerance would be expected, and this never occurs. It does not then, *a priori*, seem likely that the cause of the loss of activity can be explained on the supposition of a chemical combination. The evidence rather points to some form of destruction of the nicotine, the process being possibly of the nature of a ferment action.

Although strong evidence exists in support of the view that tolerance means increased rate of destruction, yet there is some evidence suggesting that the nicotine is taken up specifically by certain tissues, Hegei and others have shown that when nicotine is injected into the circulation of animals it disappears quickly from the blood and is taken up by the liver, from which it can be obtained by distillation.

Edmunds<sup>17, 18</sup> made similar experiments to ours on dogs. He showed that the livers of all dogs possess some power of destroying nicotine, and suggested that the destroying agent is probably a ferment. Further, he says that it is possible that this ferment may be increased in quantity by the constant use of the alkaloid, but his experiments on dogs failed to prove it. The success or failure of these experiments depends, however, entirely on having adequate controls, and these are more difficult to obtain with dogs than rabbits. Fuhner<sup>19</sup> thinks it is entirely unnecessary to assume tolerance at all. He points out that nicotine is excreted in the urine and that it is not cumulative, he neglects the clinical evidence.

Several clinicians have recorded cases showing a gradual drop in tolerance with advancing years. Turney and Rolleston both lay some stress on this. Finkelnburg says that patients, when once they have experienced symptoms of poisoning by nicotine, the particular form of which is immaterial, become more susceptible to the action, so that a smaller quantity of tobacco will reproduce the toxic symptoms. In this respect nicotine poisoning differs from most if not all chronic toxicities produced by drugs. Rolleston also draws attention to the fact that disease—for example, influenza—may destroy an acquired tolerance.

Tolerance can exist also against CO. Animals such as guinea-pigs will live for months in an atmosphere in which as much as one-quarter of their blood haemoglobin is put out of action by combination with CO. They require a tolerance which is due to an increase in the corpuscles and haemoglobin, so that the oxygen capacity of the blood becomes almost normal. If such an animal is placed in a normal atmosphere it slowly loses its CO, its available haemoglobin increases, and it appears to suffer some discomfort. It is possible that the craving of the cigarette smoker after a period of abstinence may be not unconnected with this.

#### WHY WE SMOKE

I suppose few things are more difficult to analyse than the complex which gives rise to content, satisfaction, or positive pleasure. Any incident which breaks some simple habit acquired by long usage causes not only inconvenience but positive annoyance. The ritual of the pipe and cigarette soon becomes a most pronounced habit. The short duration of the cigarette leads to the frequent repetition of a series of complicated acts, culminating in the lighting up. The ritual of pipe smoking is even more likely to lead to a tie. To finger or suck an inlet pipe, to fill it, or to be repeatedly lighting it becomes in time a series of complicated reflexes which all go to make up the tie. I am informed that tobacco put up in cartons containing sufficient to fill the pipe, thus depriving the habitue of the ritual of filling, is not popular among smokers.

The element of rhythm plays its part. It is well recognized that with certain people some form of rhythmical movement facilitates thought and gives satisfaction. Dancing, singing, and chewing gum give satisfaction partly through their rhythm, and rhythm enters largely into smoking.

Sight and smell are other important factors. Sir Robert Armstrong-Jones<sup>20</sup> says that the cloud of white smoke rising before the smoker is soothing and companionable, and it is well known that people who become blind generally, but not quite invariably, give up smoking, and that smoking in the dark does not give the same satisfaction as smoking in the light. The fragrant smell and taste of good tobacco are also stimulating, so that taste, smell, and sight all take their part in the content. The amount of nicotine in the smoke is certainly not the determining factor in the pleasure, were this so we should employ moist cigars and so the more quickly satiate our desires, aroma is more important.

Pleasure, then, depends upon at least these factors: (a) reflex stimulation from the mucous membrane of the mouth and nose, (b) the tie complex, (c) the drug action, due mainly to nicotine, and perhaps to a smaller degree to the CO in the case of the cigarette smoker. The principal action of tobacco depends on the narcotic effect of the nicotine, it produces repose and calm—what I should term a stabilizing action. The cigar and pipe smoker, during a period of abstinence, feels the want of this customary effect.

The habit of smoking is sometimes referred to as an addiction. Rolleston<sup>21</sup> discusses this question, and all it is necessary to say here is that addiction is a relative term, the most powerful drug of addiction is probably heroin, and then follow cocaine, morphine, Indian hemp, opium, alcohol, and last tobacco.

A drug addict wishes to be freed from the cares and worries incidental to existence. To do this a drug must either depress the higher faculties of mind—judgment, self-control, inhibitions of all kinds—leaving free play for the lower and emotional centres, or the more primitive and emotional centres of the brain must be excited. Nicotine would most certainly be a drug of addiction were its action confined to the central nervous system, but it also acts on the autonomic system, so that when smoking is pushed—that is, when larger amounts of nicotine are absorbed—nausea, vomiting, diarrhoea, faintness, prostration, and collapse follow. The true addict is held in bondage by the fear of withdrawal and the craving which follows it. With tobacco this does not exist, the loss of one's smoke is an annoyance, but hardly a tragedy, and few cannot, when necessity arises, entirely abstain.

#### ON CERTAIN ECONOMIC FACTORS

During the last fifteen years an enormous increase has taken place in the consumption of tobacco. In America the number of cigarettes consumed in 1914 was 3,000 million, in 1918, after the war, this had increased to 46,000 million, but the figure continues to increase, and in 1921 it reached 52,000 million. The per capita consumption of tobacco in the United States of America in 1920 was 6.3 lb., in Great Britain it was 3.17 lb. Increased consumption appears to obtain in all European countries. In Holland smoking is especially prevalent. In 1924, 2,500 million cigarettes were consumed at a cost of 33 million pounds, some statistics show that of 100 boys aged 6 years, 30 smoked, of boys between 9 and 10, 50 smoked, and of 250 boys more than 11, 220 smoked.

In Austria a pamphlet was published in 1924 by several of the most distinguished Viennese doctors to their country, which states that "Nicotine promotes arteriosclerosis and nervous diseases. In our country the cost of tobacco for one day equals the total annual deficit of all our tuberculosis sanatoria which it was necessary to close for the economy." In Germany the total expenditure for the German army in 1912 was less than its smoking bill. As a further example of the cost of tobacco to a nation, Professor Graham of Yale University has estimated that the United States of America in 1921 spent well over 300 million pounds on tobacco.

The Governments of the world are slowly appreciating

that the tobacco habit is not an unmixed blessing. England has passed legislation prohibiting the sale of tobacco to all minors under 16. Japan has a law prohibiting smoking by all persons under 20. The Austrian and German Republics are showing active interest against the further expansion of the tobacco habit, and most of the States in America have some form of legislation aimed at limiting the tobacco habit.

#### CONCLUSION

Tobacco smoking serves as a mild stimulant followed by a slight degree of narcosis, the supersensitive become calm and lose their irritability, and the dull and apathetic are stimulated. The physiological evidence clearly points to this effect, but the explanation has yet to be learned. Smoking, however, leads to digestive and circulatory disturbances. There is an increasing impression amongst clinicians that the insidious action of nicotine spread over many years of continuous absorption is responsible for at least some of the cardiovascular diseases so common in middle and later life.

It may be argued that if nicotine adds to the agreeableness of life why not use it with so pleasant? In persons of vivid sensations, to calm the commotion of conflicting sensations may be beneficial, even to the higher faculties, in the dull and listless to stimulate thought must be beneficial. It may well be that living in a civilization such as ours under the conditions of strain imposed by residence in cities the ordinary man shows in his nervous responses variations from the normal, and on such tobacco exerts a beneficial function. To what extent strict moderation in the use of tobacco leads to vascular degeneration is uncertain, is it the rule or the exception? This is the vital question to which we require an answer, and upon this answer something of the well being of the nation depends.

In conclusion I venture to suggest that the collective sagacity of this society, and that of the medical profession as a whole, could occupy itself with no subject more important to the nation than that of tobacco smoking.

## X RAYS IN THE DIAGNOSIS OF INTRATHORACIC GROWTHS

BY

STANLEY MELVILLE, M.D. Bux., M.R.C.S.,  
L.P.C.P. Barrister at Law

Radiologist St. George's Hospital and Hospital for Diseases of the Chest, Brompton

(With Special Plates)

In the pre-radiological days there were but few publications and very few discussions on intrathoracic neoplasms. Such references as there were dealt with the matter only from the standpoint of morbid anatomy. Out of 174 cases reported in 1904 by Schrit, in six only had a correct clinical diagnosis been made. It is certainly less than a hundred years since neoplastic diseases of the chest were first subjected to any systematic examination, and less than thirty years since any such examination was possible in vivo by means of x rays. In 1810 Bayle, a favourite physician of Napoleon, in his *Recherches sur la Phthise Pulmonaire*, coined the term "phthise cancéreuse," showing that even at that time morbid anatomy was not unaware of the relationship between the two diseases. The symptom complex of increased intrathoracic pressure was pointed out by Bell or Glasgow and by Stokes of Dublin, but this was as far as our forebears would go in the way of clinical diagnosis. Nor is this attitude to be wondered at, in the first place, intrathoracic new growths were regarded as being of extremely rare occurrence, and, in the second place, the hopelessness of the prognosis was not conducive to any great enthusiasm.

It is customary to divide intrathoracic new growths into two classes (a) benign, and (b) malignant. But it is only in the pathological sense that this distinction can be drawn, for every intrathoracic new growth, however benign in its pathology, will in time deprive the patient of life by a process of pressure. It seems well to appreciate this point, if for no other reason than that clinician and radiologist may be alive to the vital necessity for early diagnosis. Unfortunately, even true malignant neoplasms, as a rule, give so little evidence of their presence until they have grown to such a size as to cause pressure symptoms, or increasing breathlessness. Am I wrong in suggesting that on the very first evidence of even occasional breathlessness that cannot be accounted for the aid of the radiologist should be asked? It is said that the day is approaching when every clinician will be so alive to the interpretation of a radiograph that the radiologist will no longer be asked to carry out his proper function. I shall not live to see that day, but I am sufficiently optimistic to feel that it will be many a long day before such a complete revolution takes place, and that the wiser the clinician, the more will he demand all the expert assistance possible in arriving at a diagnosis.

#### BENIGN NEOPLASMS

The care for the most part extrapulmonary

#### Fibroma

The x ray evidence that of a well defined more or less rounded opacity, which can be shown to arise from the posterior wall of the thorax, pushing in front of itself the lung and not directly invading it. Owing to the non-irritant nature of the structure of the fibromata, there is seldom any pleural adhesion, the lung surrounding the growth but able to be separated readily. Any further growth of the tumour tends to depress the diaphragm, push the heart and mediastinum to the opposite side, and to cause compression of the adjacent lung tissue.

Diagnosis is rendered easy by the simple expedient of collapsing the lung by the production of artificial pneumothorax, when the evidence of an isolated and free tumour, which is extrapulmonary, can be made out. This expedient of compressing the lung by the admission of air into the pleural cavity has not been utilized as much as it

\*The opening paper in a discussion on this subject in the Section of Radiology at the Annual Meeting of the British Medical Association in Edinburgh July 1927.

might have been. In this country and in France it is of daily usefulness, in Germany it does not appear to have received the attention it deserves, and I venture to suggest that as a consequence many cases of fibroma have been mistaken for fibro-sarcoma, thus erroneously increasing the number of cases of primary sarcoma of the lung.

### Teratomata

Teratomata, or congenital inclusion cysts, may occur anywhere. In the thorax the most common (though the total number is not very great) are of the type of dermoid cysts, which are epiblastic in origin and contain any of the constituents of skin (hair, sebaceous material, teeth). They grow from the third bronchial cleft or from the remains of the thymus gland, and are in consequence anterior in position, differing thereby from the fibromata which practically invariably grow from the posterior ends of ribs. By a curious chance we have seen no fewer than five of these cysts at Brompton Hospital in the last twelve months, so we feel ourselves in the position of authorities on the subject (nowadays one can assume authority on such slender basis).

The dermoid cyst differs from the fibroma in being more mobile, consequently, it not only pushes the lung in front of itself, but is apt to set up adhesions between itself and the pleura, making it more difficult, if not impossible, to shell it out easily from the enveloping lung.

The diagnosis of a fairly well defined, though often markedly irregular, tumour is readily made by examining in the dead lateral plane—a matter of course nowadays, but one upon which the differential diagnosis depends. In the films which I show it will be noticed that the tumour lies close to the sternum and nearer the front than the back of the chest, when viewed in the lateral plane.

It is unfortunate that the early clinical diagnosis in intrathoracic new growths is indefinite and even misleading. In one of our cases of dermoid cyst the only clinical evidence was that of a sudden and somewhat severe hæmoptysis, indeed, the occurrence of hæmoptysis is not infrequently the sole clinical evidence, though it does nothing to assist the diagnosis as to the nature of the tumour. This is a pity, for, having regard to the positive fact that a fatal termination has to be anticipated, it follows that if surgery is to be of use the earlier the diagnosis is made the smaller the tumour and the better the outlook.

### MALIGNANT NEOPLASMS

#### 1 Primary Carcinoma

In another place I asked the opinion of my colleagues as to their experience regarding the apparent increase in the number of cases of primary lung cancer. In my own work I had to admit that this increase must be real. Nor is this contention without support, and in the following table you will see that primary lung cancer is placed, according to various observers in Germany, as high as about 4 per cent of all carcinomata found in the body.

#### Statistics of Pulmonary Carcinoma

Goldstein		127
1886	Fuchs	185

1924	Bejach	56
	Brinckmann	60
1907-11	Kolszewski (Berlin)	

*Fortschritte f. R., January, 1924*

"The figures represent the percentage of primary lung carcinoma relative to primary carcinoma of all other organs. The figures correspond to the year in which the statistics were compiled and the name of the compiler. Reckoning from the post mortem statistics a similar increase appears to have occurred in the total number of lung carcinomata. According to the comprehensive statistics from Kries's *Ungesch. prim. Lung. Carcinomata* is four times as common as primary lung sarcoma."—*Fortschritte f. R.* March, 1924.

The question to which I would invite discussion is as follows: Is this increase real, or can it be that many cases which we now recognize as carcinomata have in the past been mistaken for pulmonary tuberculosis, and especially of the fibroid type? There is some trustworthy proof of this. Friedländer and others have found squamous-celled carcinomata in the walls of an old tuberculous cavity. The experienced chest clinician, and radiologist too, knows that tuberculous infiltration may accompany neoplastic disease. Following irritative conditions, as, for instance, in the cobalt miners of Schneeberg, the subjects of chronic interstitial pneumonia and pneumoconiosis, primary lung carcinoma is not uncommon. This possibly helps to appreciate the German figures.

Almost without exception new growths of the lung have an acute history to start with, or set up acute bronchial conditions. Primary cancer of the lung usually starts in the mucous membrane of a large bronchus close to the bifurcation of the trachea. A malignant growth may be of quite large size before it gives any positive evidence of its presence. As it grows outwards it tends to compress the lung above itself, the limit of the neoplasm and the adjacent lung tissue being difficult to make out, the growth at first is strictly delimited by the interlobar fissure. From the situation of the growth it will be appreciated that the earliest clinical evidence is that of bronchial stenosis and the presence of "silent" lung above the growth. There is a definite tendency for the heart and mediastinum to be drawn towards the affected side, and this is a diagnostic feature of no little importance. Involvement of the phrenic nerve frequently follows, the diaphragm being raised and finally paralyzed. A primary carcinoma in the upper part of the chest is more readily recognized than when the lower zone is the seat of the trouble. The density of the mass and its sharp delimitation by the interlobar fissure can only be confused with a massive lobar pneumonia, in which, however, the history will assist. In the lower zone, however, there is much more rapid pleural involvement, the growth is less sharply defined, and the occurrence of secondary degenerative changes is much more rapidly met with. In all cases pleural involvement and degenerative changes, simulating bleeding down and abscess formation, tend to make the distinction between cancer and other inflammatory affections more difficult. The degenerative processes are by themselves impossible to distinguish from those of gangrene or bronchiectasis.

#### 2 Sarcoma

I am anxious to learn whether primary sarcoma of the lung (as opposed to lymphosarcoma arising from the mediastinal glands and therefore primarily mediastinal) does really exist. Adler entirely examined ninety cases, and came to the conclusion that hardly any of them appeared to justify their separation from carcinomata. A metastasis from some undiscovered primary focus (for example, the prostate) may well account for some of the suggested primary lung sarcomas.

#### Hodgkin's Disease

The diagnosis of this disease is not, as a rule, difficult, for it is but seldom that glandular enlargements are met with only in the mediastinum. The blood picture is not of great assistance, but moderate eosinophilia, progressive anaemia, with increase in the leucocytes, and frequently pyrexia, are all helpful in the diagnosis. The x-ray picture is that of a fairly well defined mass in the mediastinum, simulating any other mediastinal growth.

#### New Growths of the Mediastinum

Surely the most difficult part of our work is the differential diagnosis between the various tumours which may be encountered in the mediastinum. Some years ago the best and kindest thing that could be said of the radiology of the chest was that it was of great value in the diagnosis between aneurysm and neoplasm, and that the diagnosis was simple. All one had to do was to place the patient in front of a fluorocent screen and the diagnosis was simple. How delightful if this were so! But I am leapt out! How delightful if the radiologist, and all speaking to learned and experienced radiologists, and all will agree with me that the matter is not quite so simple.

as it seems. How often have not we had to wait in order to decide whether a large pulsating tumour in the mediastinum would turn out to be a large aneurysm of the arch or a sarcoma growing from the mediastinum? And mind you not infrequently the matter was further complicated by there being a positive Wassermann reaction. Not does the clinical examination assist us. Most of the signs are alike in both, and these are due chiefly to pressure effects. Cyanosis, venous engorgement, and signs of collateral circulation are possibly more common in neoplasm. The time factor is of service. If signs have persisted for eighteen months or thereabouts, the evidence is in favour of aneurysm.

Hare, in an excellent analysis of 520 cases of mediastinal disease gives the following table:

Cancer	134
Sarcoma	90
Lymphoma	21
Dermoid	11
Hydatid	8

The rest were composed of inflammatory disease, and included instances of hyponia, enchondroma and gumma.

There are three tumours in the mediastinum which I should especially like to mention: (1) Aneurysm of the thoracic aorta (arch). (2) Sarcoma growing either from the mediastinal glands, or (as in a case under my care) as arising from the remains of the thymus gland. (3) Malignant tumour growing from the thyroid.

(1) *Aneurysm of the thoracic arch*.—I need not labour the question of diagnosis in this condition. It is obvious that the history must be taken into account, the absence or presence of a positive Wassermann reaction noted, and examination in the lateral oblique as well as in the postero-anterior plane, the former showing marked tendency to "clubbing" and thereby differentiating it from anything else.

(2) *Sarcoma of the Mediastinum*.—In this condition there is often a pulsation (transmitted) equal to, if not greater than that in the case of a large and consolidated aneurysm. To decide whether pulsation is transmitted or not is truly a difficult matter. A large mediastinal sarcoma frequently invades both sides of the mediastinal space, causing compression or deviation of the trachea, definite signs of compression, interference with the circulation, etc. Differing from aneurysm, it seldom causes erosion of the bony structures; indeed, the diagnosis of aneurysm is frequently determined by this result.

(3) *Tumour Growing from the Thyroid*.—Examination in the lateral plane will reveal a tongue-like process growing downwards and forwards and depressing the arch of the aorta. Such growths are of extreme rarity, but the foregoing evidence clearly demonstrates the situation of the growth.

At the conclusion of his paper Dr Stanley Melville put forward the following three questions for discussion:

Is it held that there is any definite relation between primary carcinoma and pulmonary tuberculosis?

What is the opinion of the Section on the rather vital question of the increase of malignant disease? Is his real or are we now beginning to diagnose tumours of the lung, which in pre-radiological days were regarded as pulmonary tuberculosis and especially of the fibrotic type?

What evidence is there of definite primary sarcoma of the lung?

#### DISCUSSION

Mr C THURSTAN HOLLAND (Liverpool) said that too much was expected from radiology as regards the differential diagnosis of conditions of the chest. It was easy to demonstrate various growths in the chest by radiography, but differential diagnosis was extremely difficult, and in some cases impossible. In the attempt to distinguish between aneurysm and growth mistakes had often been made both ways. In doubtful cases he ascertained whether in any position of the patient wave-like pulsations could be seen on the edge of the shadow, if such were present he reported that it was a case of pulmonary aneurysm but it did not follow when these were not seen that there was

no aneurysm there. It might not be possible to get the patient into such a position that the wave-like pulsation was visible, or there might not be any wave-like pulsation. With regard to the first of Dr Melville's three questions, Dr Thurstan Holland had never seen anything either in the x-ray department or in the post-mortem room which would have led him to believe that there was any direct connexion between pulmonary tuberculosis and primary carcinoma, nor that malignant disease of the lung was increasing. It was much more likely that accuracy in diagnosis had improved so that more cases had been collected, and thus the increase was apparent rather than real. He did not think he had ever seen a case of primary sarcoma of the lung though he had seen secondary sarcoma many times. He agreed with Dr Melville about differential diagnosis, but one or two points had not been mentioned—for example the drawing off of fluid in the chest, which had often obscured a growth. Certain American workers had recently stated that, by giving doubtful cases a definite dose of x-rays and taking radiographs under standard conditions as a result of the action of the rays on the presumed growth they had often been able to make a differential diagnosis and had frequently obtained valuable information. There were a large number of intrathoracic cases of the kind not diagnosable by x-rays alone. Only by the collaboration of the clinician and the radiologist and only when the greatest care was taken, was accurate differential diagnosis possible.

Dr A I BIRCHALL (Manchester) emphasized the absolute need of co-operation between the clinical side of medicine and the radiologist. The radiologist who worked merely in his own department would make mistakes, and on the other hand much clinical medicine should be rewritten nowadays in the light of radiology. He asked whether anyone present had demonstrated tracheal tugging in the case of an aneurysm.

Dr D CAMPBELL SCOTIE (Glasgow) said that as a radiologist at a children's hospital his experience gained in dealing with perhaps 14,000 chest cases in children up to the age of 12 was that primary tumours of the chest were very rare; he had seen only one case of secondary tumour.

Dr L A ROWDEN (Ireels), speaking of the diagnosis of chest tumours, said that radiologists in his part of the country always gave an opaque feed to see what effect the growth had upon the oesophagus. The method was very helpful in certain cases.

Sir HUMPHRY ROLLESTON (Cambridge) agreed that it was important that the clinician should go into the radiological department and the radiologist into the post-mortem room. With regard to tracheal tugging he had always had a doubt as to whether he was applying the test in the proper way, and he believed that the difficulty was not so much in saying whether there was tracheal tugging as in deciding whether it was due to an aneurysm, or to mediastinitis or to a mediastinal tumour.

Lord DAWSON OF PENZANCE suggested that it would be worth while trying conjoint teaching. When there were clinical lectures in the wards the radiologist might be invited to come to discuss the matter from his own point of view. The radiologist was however apt to think that an audience in front of him was a meeting of radiologists and he did not always sufficiently realize that clinical teaching had to be short and succinct so as to allow five or six cases to be dealt with in two hours. The difficulty would disappear with more frequent co-ordination which would benefit both clinician and radiologist, each being able to see the difficulties of the other. Tracheal tugging existed but no one would be so foolish as to diagnose an aneurysm by this alone, since aneurysms often occurred without it. The advances of radiology were greater than those of almost all other branches of medicine, but the great difficulty was the expense. Unless a picture was extremely good the clinician was apt to be misled. He had found it very difficult sometimes even to tell an advanced case of tuberculosis from certain types of growth.

Dr N S FINZI (London) said that it was very difficult sometimes to decide whether a sarcoma started in the mediastinum or in the lung, whether it had involved the lung and spread into the mediastinum, or vice versa. One case he had encountered was very definite because the growth was in the apex of the lung. On other occasions he had felt almost certain that the primary growth was in the lung and had spread into the mediastinum and involved the walls of the aorta. He had seen at a necropsy a case in which the walls of the aorta and of the oesophagus were involved, and it was very difficult to prove that the condition did not start in the mediastinum.

The PRESIDENT (Dr Woodburn Morrison) said that radiology was a definite part of clinical examination—an extension of the method of inspection, he would like to see it mentioned in all textbooks under the head of "physical examination for clinical diagnosis." The radiologist was purely a clinician, and the clinician was only occasionally a radiologist. The ideal would be for the clinician to be an expert radiologist, but until that time came, and until the clinician would willingly undergo the labour of acquiring a knowledge of radiology, the only course was co-operation. The term "radiological diagnosis" was often used and seldom justifiable.

Dr MELVILLE, in reply, doubted whether his questions had been answered. Dr Finzi was the only speaker to tackle the question of the site of origin of a sarcoma, and his conclusions were disappointing—merely that the sarcoma might have started in the mediastinum. So much was heard of primary sarcomas of the lung, and yet hardly anyone in that meeting could say definitely that he had seen such a thing. It was quite conceivable that a small focus in the postero-lateral ovary might have been overlooked, and metastases in the lung, which would be more evident, had occurred. True primary sarcoma of the lung was, he maintained, to use a Scottish term, "not proven."

## X RAYS AND RADIUM IN THE TREATMENT OF CARCINOMA OF THE BREAST \*

BY

N S FINZI, M B Lond, D M R E Camb,  
Medical Officer in charge of the X Ray Department,  
St Bartholomew's Hospital  
(With Special Plate)

Certain considerations, as to the natural history and spread of cancer of the breast, influence so largely the question of treatment that we must spare a few moments to discuss them.

With the rarest exceptions, medical men are agreed that cancer starts as a local disease, or at any rate a local manifestation. In most types of the disease it tends sooner or later to spread—at first by the lymphatics and lymphatic glands, and later, in some cases, by the blood stream. If the disease is completely removed while it is still local, whether by surgery or by radiation, the patient will be cured. When, however, the disease has spread beyond the area removed, or beyond the area to which a sufficiency of radiation has been given, it recommences to grow, and tends subsequently to kill the patient. In rare cases, in old people, the disease remains localized, and shows no tendency to any distant spread.

In an occasional case, of the most extraordinary rarity, the disease, though well advanced, may completely disappear, perhaps for a time only. I have seen two such cases in the course of many years, during which I have seen thousands of breast carcinomas. One of these cases was shown at a society, and the other occurred in my practice at St Bartholomew's Hospital. We have reason to fear that, after being well for more than two and a half years, the latter is beginning to recur.

Obviously the mode and directions of spread are extremely important, and we must therefore carefully consider the lymphatic supply of the breast. It must be remembered

that the disease can pass either with or against the direction of lymphatic flow, and it has been shown by Sampson Handley that cancer cells may die out in one part of a lymphatic and cause it to shrink down to a fibrous thread, while further on, in the same lymphatic, they may develop into a tumour. The fact that cancer cells can be traced along the lymphatic channels seems to show that it is the cells themselves which spread the disease for the cells of normal tissues do not appear to enter the lymphatics.

The lymphatics from the mamma pass mainly into the pectoral group of axillary glands, and occasionally directly to the subclavicular glands. Lymphatic cells also pass from the inner part of the mamma into the intercostal spaces and so into the sternal lymph glands. Lymphatic vessels from the upper part of the pectoral region also pass directly to the supraclavicular glands. The lymphatics from the pectoral group pass to the rest of the axillary glands, the subclavicular glands, and the supraclavicular glands, and thence to the glands in the posterior mediastinum. Those from the sternal glands pass into the anterior mediastinum and thence into the posterior mediastinum. The lymphatics on the surface of the upper abdomen are also connected with the pectoral lymphatics.

Thus it will be observed that, when the primary growth is in the outer part of the breast, further trouble may be first expected in the axillary and the subclavicular glands, and later in the supraclavicular glands and the posterior mediastinum. If it is in the inner part of the breast, the inner end of the intercostal spaces and the anterior mediastinum are the danger zones. If in the upper part of the breast the supraclavicular glands must be suspected. In practice a recurrence under the costo-cornoid ligament, very difficult to feel but causing much swelling of the arm and forearm, is very common, probably almost all, if not quite all, the cases of great lymphatic obstruction in the arm after carcinoma of the breast are due to this cause. In advanced cases the disease often invades the pleura, possibly by the sternal glands or the intercostal glands, possibly by way of the mediastinum. It is obvious that the cells will eventually reach the blood stream by the thoracic duct.

Involvement of the mediastinal and tracheo-bronchial glands may often be discovered by a skiagram, as also pleural metastases and blood disseminated metastases in the lungs. They obviously cannot be seen in the earliest stages, but only when they have formed definite tumours. They tend to have a typical rounded appearance. For this reason, and also for future reference, skiagrams, both anterior and antero-lateral, should be taken of every breast carcinoma before a ray treatment.

### ACTION OF RADIUM RAYS AND X RAYS IN CARCINOMA

The alpha and the beta rays of radium need only be considered shortly. The former have, as their low penetrating power would indicate, apparently no value in the treatment of carcinoma of the breast. With beta rays the matter is not so definite, but anyhow much better results have been obtained by gamma rays and by x rays in this disease, so that I shall not deal with the beta rays in this paper.

*In vitro* it is found that there is a certain minimal dose which, when applied to experimental growths, will inevitably prevent their development. This is the "lethal dose," and will cause the growth to be absorbed by the tissues of the animal into which it is implanted, and it will then immunize this animal against future implants of a similar growth. Larger doses of rays will equally prevent development of the irradiated graft, but will not immunize to the same extent, so that, when about twenty times the lethal dose has been given, the graft no longer immunizes. Doses smaller than the lethal dose will reduce the ratio of successful implantations without preventing them in every case. The lethal dose is much higher than can be applied to living tissues without causing their necrosis.

The irradiation of the tissues into which a cancer graft is to be made will reduce the percentage of successful takes compared with controls. When the tumour and growth are irradiated together the latter will disappear with a dose of the order of half the lethal dose.

\* The opening paper of a discussion in the Section of Radiology at the Annual Meeting of the British Medical Association, Edinburgh, 1927.

FIG 1—Primary bronchial carcinoma

FIG 2—Primary bronchial carcinoma Note para-lysed diaphragm on affected side.

FIG 3—Primary carcinoma (same case after in-jection of lipiodol and production of artificial pneumothorax) showing tension of bronchus

FIG 4—Metastatic carcinoma of lung Secondary to a primary focus in ovary

FIG 5.—Dermoid cyst.

FIG 6—Dermoid cyst (Same case in lateral plane.)

FIG 1—Acute burn Before treatment

FIG 2—Acute burn Three weeks after treatment

FIG 3—Acute burn Six weeks after treatment

FIG 4—Acute burn Two and a half years after treatment

FIG 5—Chronic burn Three months after termination of six months treatment

FIG 6—Chronic burn Same case two years later

The action of the rays in a human being varies with the type of disease. In general the more rapidly growing the neoplasm the more readily will it succumb to irradiation but, as the rapidly growing forms spread more quickly a wider area and more distant glands will need to be treated in such cases, and a greater number of successful results will subsequently be spoiled by distant metastases. With the rapidly growing forms the effect of the rays is rapid, a change being seen in a day or two, while in the more slowly growing forms the changes may take a good many weeks.

The type of ray used also has an influence on the type of reaction. As the wave-length of x rays decreases so their effect takes longer and longer to appear. With gamma rays, however, the effect appears in about the same time as x rays produced by 150 kilovolts continuous current. I am distinctly of opinion that the carcinomata and epitheliomata respond better to x rays, the shorter the wave-length if full doses are given. Consequently the radium gamma rays are the best provided that they are applied in sufficient quantity. With some types of sarcoma it is probably a different story. The lymphosarcoma probably responds at least as well to medium wave-lengths if applied in sufficient concentration.

#### *Comparison of Radium Gamma Rays and X Rays*

With modern apparatus x rays can be obtained in large quantities to rival which we should have to use what we at present regard as enormous quantities of radium. On the other hand, this can to a certain extent be counteracted by the facility with which the radium can be applied for prolonged periods, even continuously for many days. In the rare instances in which comparatively large quantities of radium can be secured and they are used in a similar way to x rays they are not concentrated into a point focus, but spread over a large radiating surface, with the result that the relative depth dose is greatly increased. Much more commonly the radium is used considerably nearer the surface than an x ray focus can possibly be placed but spread over a large area. It is left in place usually for a number of days or even weeks.

The radium rays are much more penetrating and for the same amount of damage to healthy tissues seem to exert more effect on carcinomata than x rays. However, with radium used in this way, the underlying lung must get a large dose and subsequent lung damage may be expected. With x rays on the other hand the use of a glancing method (subsequently described) will to a large extent prevent this.

Radium used for external applications therefore has the advantages compared with x rays, of more penetrating rays of a more suitable wave-length, multiple foci or a series of large foci, and continuous application. Its disadvantages are that it is not so easy to give an even dose over the large deep area required in breast carcinoma, and that it is not possible to avoid injury to the lung.

Radium is used also in quite another way—namely by burrowing a number of radium containers in the tissues. As a rule hollow needles containing either radium salt or radon are employed. When small quantities are used in each needle for a week or more the radon is at a very decided disadvantage compared to the salt, for in order to obtain the same total dose a considerably larger amount of radon has to be used at the start and the effects are different. The needles are used deep to the growth if possible or in its deeper layers not in the middle of it. The gland areas are of course needled at the same time. X rays are not used in any way comparable to this.

I have an impression that the results with buried radium are better than with external method provided that the wound remains aseptic. This can only be accomplished by meticulous care owing to the damage inflicted by the radium on the tissues. I have advanced in explanation the hypothesis that around the radium needles there are zones in which the cells of the growth receive a true "lethal" dose and that the absorption of these may weaken the resistance of the remaining cells to smaller doses of rays.

#### *TREATMENT BY IRRADIATION ALONE*

##### *1 Primary Growth Localized in Breast no Palpable Glands*

(a) *Operable* (as far as local condition is concerned).—Should we treat an operable case with radiations when surgery is not contraindicated? The answer is. At present, only if the breast is subsequently removed. The loss of time possibly two months, is probably more than compensated for by the diminished likelihood of dissemination of the growth at the operation. So far we have treated very few truly operable cases either with radium or x rays, and we have not yet had the breast removed after complete disappearance of the growth and so proved the absence of cancer cells\*. Therefore we cannot say that our technique is yet good enough to recommend the treatment of the disease by irradiation alone when it is operable. When other causes contraindicate operation the case must be considered as inoperable and treated as such.

(b) *Inoperable*.—We have succeeded in a number of cases in rendering the growth inactive for long periods by x rays but we have seldom observed its complete disappearance. With radium needling, properly done, our results are more encouraging. In a large proportion the growth completely disappears, and the only questions then are whether all the cells have disappeared, whether the gland areas have received a large enough dose, and whether the mediastinum is also involved.

##### *2 Primary Growth in Breast Palpable Glands in Axilla*

The radiation treatment of such a case depends largely on the x-rayographic evidence. If the typical rounded mediastinal glands are seen nothing but mediastinal treatment is of any value and as this usually prevents a sufficient dose being given to the breast and axilla the question of surgical help must be considered. If the mediastinum is not demonstrably involved, it is best to assume for the time being that it is free and treat the breast just as if operable with the exceptions that the subclavicular and probably also the supraclavicular regions must be treated and, if the growth is in the inner part of the breast, the inner ends of the intercostal spaces also. If the mediastinum is subequally found to be involved, it can then be treated by x rays.

##### *3 Primary Growth with Supraclavicular Deposits on the Same Side*

Such cases must always be regarded as having the mediastinum infected even when too early to show with x rays and unless mediastinal treatment can be adopted together with correct dosage of the breast, axilla, and supraclavicular regions with x rays no permanent success can be hoped for. Combined radium and x ray treatment might be used in some of these cases.

##### *4 With Definite Mediastinal Involvement*

Until comparatively recently I regarded these cases as almost hopeless and attempted nothing radical. I have, however, had several cases which have done so extraordinarily well that I no longer despair. It is now more than three years since I treated the first by my present technique and the patient is still well. Another has been under treatment over two and a half years and has had very extensive recurrences but has recovered in a miraculous way.

##### *5 Treatment of Distant Metastases*

Bone metastases are usually very painful and there may for a time be only one or two. Treatment of such metastases gives so much relief that it cannot be refused even though it is certain that the patient will ultimately succumb to other metastases. Even when the pelvic bones are riddled with disease I have observed much relief from radical treatment lasting often for six months or more. There are of course limits and generalized disease, masses in the liver, and so on, should not be treated by irradiation.

\* This has now been done (October 1927).

## RECURRENTS AFTER OPERATION

**Local**—The general lines of treatment of these will be similar to the methods of dealing with a primary growth detailed already.

**Distant**—In the axilla, the coracoid region, and in the mediastinum, the treatment will be as when the primary growth is present. Metastases in distant parts must be dealt with on their merits, they are worth treating on account of the great relief from pain and disability, though when once they are deposited in distant bones there is no hope of ultimate cure. In that band of us all, the recurrence in the sternum, pelvic bones, and lumbar spine, complete relief of pain can often be given for many months, and I have seen a patient live for three years after a recurrence in the lower end of the femur had been cured by x-ray treatment.

## TREATMENT BY RADIATION COMBINED WITH SURGERY

There are many problems to be discussed under this heading.

## 1 Radical Operation Preceded or Followed by Irradiation

Surgery has had so long an innings, and the procedure has become so standardized, that the statistics should be fairly definite. There are, however, only few figures giving five-year results, and these seem to vary considerably. With radiation used in addition, it is extremely difficult to determine the results. To start with, the procedure is not standardized, consequently if it is any good at all, obviously the best method will give the best results. It is my personal belief that thorough irradiation improves the results, but that small and ineffective dosage hastens the appearance of recurrence, though it probably cannot induce it. One great difficulty in treating these patients is the mental attitude. The surgeon may make the patient believe that it is necessary to do a big operation to remove a "harmless little growth" or "an inflammatory focus," but this leaves the radiologist little chance of explaining that radium or x-rays, with all their attendant expense, must be used to diminish the possibility of its return, especially if radical methods are used.

The Erlangen school holds that irradiation after a radical operation is of no value owing to the disturbance of the blood supply, but the rarity of local recurrence in treated cases, compared with its comparative frequency in untreated cases, leads to the belief that the treatment is beneficial.

The prophylactic use of x-rays may be either pre-operative or post-operative.

(a) **Pre-operative**—The basis of this treatment is that the rays will damage the carcinoma cells and so prevent their development if any are scattered in the wound. The use of large doses, however, may prevent the wound from healing, especially if there is much tension on it, and there may result either sloughing or complete failure of the cut edges to unite. Having had two cases in which one of these events occurred, I have not dared to employ it again, though the principle seems sound. The use of small doses to stimulate the defence mechanism is a very questionable proceeding.

(b) **Post-operative**—Radium can be used either in some form of moulded apparatus or in the form of plaques. It is advisable that there should be a space between the radium and the skin in order to get even irradiation at the deeper levels. It is doubtful, however, if the axilla will get so effective a dose as with x-rays, and it is not possible to protect the lung. X-rays are applied to the pleural area by a glancing method, and to the supra-clavicular and coracoid regions from the front and back. I prefer to separate the two treatments by an interval of three months so that the axilla is treated twice, the first area being that in which recurrence is the more likely from the original position of the growth.

As to dosage in prophylactic treatment, I hold very strongly the view that the methods used should be exactly the same as when a demonstrable recurrence is present, and the doses just as full. We assume that there still remains some disease and use the most thorough methods to eradicate it. It has lately become the custom in

Germany to split the dose into smaller treatments at long intervals. This is based on the following theory. Experiments with beans have shown that there is a certain minimal dose which will kill a growing bean. If one third of this dose is applied and repeated on two subsequent occasions at some weeks' interval, the bean grows normally. Now, if a resting (dys) bean be treated in the same way with three fractional doses it will fail to develop. It is assumed that the cancer cells in a prophylactic treatment are in a similar resting stage and that they can be killed by summated doses without harming the remainder of the tissues. I disbelieve this theory because I think it is wrong to consider the cancer cells as in the same state as the resting bean.

A quite different method of prophylactic treatment is the leaving, during the operation, of small radium tubes in places where recurrences are most likely to take place, or rather, in the lymphatic path along which the cells are most likely to spread. The placing of the radium tubes will depend upon the position of the primary growth. They are most usually placed in the supraclavicular and the subclavicular regions, and in the muscles at the inner ends of the upper three or four intercostal spaces. My only criticism of this method is that its zone of action is limited, and, to get at all a large dose, it is necessary to give too much in the immediate neighbourhood of the radium.

## 2 Local Removal of the Growth and Irradiation

My view on this is that, if we can get rid of the deposits in the axillary glands, it is almost certain that we can also get rid of the primary growth, and its surgical removal is therefore an unnecessary disturbance. When the mediastinum is involved, however, it may facilitate the technique to remove the breast without doing an extensive dissection. It is best done after the radiation treatment to diminish the likelihood of insemination. Each of such cases should be carefully considered by the surgeon and radiologist in consultation. Local removal may also be performed in cases apparently cured by radium or x-ray treatment, in order to be sure that the technique is good enough to cause all the carcinoma cells to be absorbed, but if once this fact is established it will no longer be necessary.

## 3 Exposure of the Growth, Irradiation, Closure

This method has been proposed to get over the difficulty of the dose of medium x-rays being limited by the sensibility of the skin. I have no experience of the use of x-rays or radium in this way, radium buried in the tissues will be considered separately. Similarly the open wound might be treated after a radical operation, but anything like a full irradiation would probably prevent proper healing.

## 4 Radium Surgery of Access

The technique for the introduction of the needles in a breast case is not simple and considerable practice is needed to get satisfactory results. Only a study of the skiagrams of his cases will enable a surgeon to realize how difficult is the position of the needles from what he had imagined. The supreme importance of asepsis cannot be magnified. The supreme importance of asepsis cannot be too greatly emphasized, and it is no ordinary asepsis that is needed. Normally the tissues can deal with quite a large number of bacteria, but they are rendered much more vulnerable to bacterial attack after being exposed to more vulnerable to bacterial attack after being exposed to large doses of radium. Therefore far radium rays in the large doses required. Therefore far greater precautions must be taken than with healthy tissues—as much care as is necessary to keep the tissues of a diabetic free from sepsis in an operation.

The treatment of recurrences by radium needling is only sound when the recurrence is absolutely local. Multiple recurrences are generally evidence either of some deeper focus or of extensive superficial invasion, and need to be treated accordingly.

## AFTER-EFFECTS OF RADIATION

## Immediate

Some patients suffer from sickness, which may be considerable if the dose is large. This can be much diminished or even abolished by certain precautions. In the first

place spreading the treatment over several days is very effective. Next the avoidance of direct radiation passing through the chest helps a great deal when it is feasible. Then having well ventilated treatment rooms, from which all corona discharge is eliminated also assists considerably. The administration of 10 grains of chloroform before the treatment, and three times a day during it, is also of assistance. Lastly, the patient should be advised to drink plenty and to eat very little during the course of treatment. When the treatment is divided, the amount of radiation must be increased.

#### Subsequent

A certain amount of erythema of the skin must be obtained if the results are to be successful and this should be just short of vesication. If the treatment is repeated, telangiectases may be expected to form a year or two afterwards and if several times repeated in full doses, they are inevitable.

When the skin is much changed by several treatments it is very susceptible to damage by any trauma—even a very hot bath will do it—and to infections when so damaged. These infections cause a very intractable ulceration, and the best treatment is to get them in the early stage, cultivate the infective agent, and then give the patient vaccines from this. Zinc ionization is also useful in healing the ulcerations.

When effective doses of rays are used on the chest wall, it is difficult to avoid the lung receiving such doses. Many such cases will then develop a characteristic lesion of the lung. It does not occur in all cases unless the dose has been very large, and it may be due to the waking up of old disease foci which exist in most lungs. The acute form is produced by a large dose of radiation delivered over a few days, and shows itself first of all as a pneumonic patch in the lung with slight displacement of the heart and mediastinal contents towards the affected region. This displacement gradually becomes more marked and eventually typical mottlings appear in the affected lung. Later the typical appearance of bronchiectasis develops, generally however without the symptoms of this condition (Figs 1, 2, 3, 4). In the chronic form, caused by irradiation at intervals over a long period, the changes are similar except that the pneumonic stage is not observed. In the final stage the patient is unconscious of any abnormality as a rule, but in one rare case a typical bronchiectasis remained (Figs 5, 6).

#### TECHNIQUE

##### X Rays

In order to avoid the lung damage referred to I devised a method with x rays, which I published at the Bilingual Congress of Radiology in London in 1922. Holfelder of Frankfurt subsequently devised a similar method which in some ways is an improvement. The principle of each of these is to use the rays at a tangent to the chest and so to avoid damage to more than the superficial parts and the apex of the lung in both of which it is inevitable. The rest of the lung is protected by lead or other opaque material. The disadvantage of this method is that rays are kept away from the mediastinum so that skiagrams of the chest must always precede the treatment to show whether there is any obvious mediastinal involvement and if such be the case a different technique is employed. If the mediastinum is not involved the tangential method has the advantage that it is much less likely to cause radiation sickness than large doses on the mediastinum.

The supraclavicular region is treated by separate fields, front and back, either at the same time as the pectoral region or at a different time. I prefer the latter method, because I then give the axilla and coracoid regions a second dose and as these are the parts most infested by recurrences, the results are better. Ten or twelve weeks should elapse between the two treatments.

The focus skin distance I use in each of the above is 50 cm., but more will be required if the radiation is less penetrating. I use continuous high tension current at 170-185 kilovolts (Peeke tables) which is the limit that most tubes will stand. It is found that above 160 kilovolts the dose which will give a skin erythema is enormously larger than below.

For mediastinal treatment I use a number of fields converging on the mediastinum for preference giving half the treatment on one pattern and the other half on another pattern over-

lapping this. The focus skin distance is only 30 cm., and it is not found necessary to give a full erythema dose to any one area. The supraclavicular regions are taken in, whether enlarged glands can be felt in them or not.

Whatever method is employed I have obtained the best results, so far as x rays are concerned, with the hardest rays.

#### Radium

(a) *Needling*—Long radium needles of an active length of 6 cm if possible, are introduced into the deeper part of the breast or of the tumour in parallel formation being adhered to and each needle being about 1 cm from the next those, however, on the outer edge being slightly closer together. Needles are also introduced into the axilla in similar formation when a primary tumour is being treated, and if possible into the coracoid and supraclavicular regions, especially if the axillary glands are palpable because the disease has always passed beyond the palpable glands. The needles are made of platinum, with a wall 0.5 or 0.6 mm thick and contain 0.5 or 0.6 mg of radium per cm active length. They are left in for from six to ten days.

(b) *Combined Method*—After a radical operation tubes are left at the inner end of each of the upper intercostal spaces—say 10 mg with a 0.5 mm platinum filter for two days—two or three others in the supraclavicular region, and another tube below the clavicle.

(c) *External Applications*—Either a mould of special wax is made to fit tightly on to the whole breast area or a splint in some light material such as celluloid or special thin wood, is made. In the former case the radium tubes or needles are distributed evenly on the wax which is usually some 3 cm thick or even more. When the splint is used little blocks are stuck into it which carry the radium at the requisite distance from the skin. When very large quantities of radium are used necessitating considerable protection, they are usually carried on a separate apparatus allowing universal movement—something like an x ray tube stand. Placing the radium directly on the skin does not relieve a sufficiently large depth dose and is out of date.

#### RESULTS

On the whole the material with which we have to deal is so bad that our results cannot be good. By the use of radium needles, however as described above, in a series of cases not so advanced as the bulk of cases supplied, the results are very hopeful indeed. With x rays we have generally had later cases to treat, and while the disease can usually be kept in check for a long time, complete disappearance of the growth is uncommon. Many such cases also are subsequently lost from distant metastases, usually in the pelvis and lumbar spine. A local recurrence of the disease, after apparently complete disappearance, makes us think that the technique is at fault and we wonder whether it would not be wise in all cases to give a second treatment, possibly using a somewhat smaller dose than the first time as a prophylactic.

I have seen several cases with what seemed to be definite mediastinal spread, generally with deposits in the supraclavicular glands or other places as well, in which all external evidence of the disease has disappeared, the shadows in the mediastinum have become smaller and lost their characteristic outline, and so far the patient has remained well for two or three years or more. These are rather unexpected and I think we must regard them as lucky, though we always expect to see improvement.

On the whole therefore, palliation and prolongation of life are the rule, cure the exception. From what we have seen it is obvious that better results may be expected by obtaining the cases in an earlier stage.

When a case is not too far advanced radium seems to give better results than x rays.

There is no question that we could be supplied with a better type of case. The surgical waiting lists at most hospitals are long and a certain number of cases have advanced beyond the curable stage in the weeks during which they wait for a bed. The comparatively short time required for their irradiation would spare more beds for keeping the waiting list short, and eventually more lives would be saved. The use of radium needling in earlier cases has immediately shown marked improvement in the results and such methods, followed by extirpation if desired, seem to offer a better chance of cure than operation with subsequent irradiation. On the other hand, prophylactic radiation must not be withheld when operation

is the method preferred. So long as surgical removal of a cancer is a recognized method of treatment radiation must also find a place.

## DISCUSSION

Dr J H DOUGLAS WEBSTER (London) advocated the closer co-ordination of radiological and surgical treatment. He thought that increased emphasis on the value of radiology, by diminishing the certainty that operations would be advised, would result in nervous patients seeking treatment earlier for small, painless lumps in the breast, and would thus improve the chances of cure. He believed that in many cases surgical intervention hastened a fatal issue. Local recurrences were less frequent when radiation treatment was commenced within two to four weeks after a surgical operation. Prophylactic x-ray therapy was of the greatest value after admittedly incomplete operations—as, for example, when the axillary glands could not be wholly cleared. Local improvement followed radiation treatment, even in inoperable cases, when surgical treatment was sometimes rendered possible thereby. The speaker pleaded for the extension of facilities for x-ray and radium treatment of cancer of the breast, since the results were often better than those of surgery. In his opinion operations ought to be forbidden in the case of active tumours which had not been sterilized by preliminary radiation.

Dr A E BIRLEY (Manchester) expressed his admiration of Dr Finzi's work, and recalled a memory of seeing him in the midst of a litter of broken x-ray tubes and other apparatus making an effort to get more intense radiations. Everyone had seen marvellous results with x-rays and radium, and occasionally people had seen similar benefit without either. There were many types of cancer, and some were amenable to quite local radiations, while others were not. He mentioned two cases which had been operated on many years before and in which there had been supraclavicular recurrence. He decided to treat one patient with rays of ordinary wave-length and the other with deep therapy. The second improved remarkably, and they were very cheered to see the growth disappear, but the patient was dead within six months. The other patient, who was treated superficially, lived much longer. It often happened that the immediate results were good, but the ultimate results poor, he had therefore become conservative and could not share the optimism of either Dr Finzi or Dr Webster. While all could obtain wonderful results with x-rays, it was essential that before they tried to do any good they must ensure that they did no damage. With regard to post-operative treatment, he noted that Dr Finzi used the maximum dose which the tissues would stand, the speaker could not see the necessity for going to the length of damaging the skin. One extremely important point in post-operative treatment was the period when x-ray treatment should be started, if begun within a fortnight or three weeks of the operation there seemed to be a far smaller number of recurrences than in cases in which it was delayed longer.

Professor M R J HAYES (Dublin) submitted figures showing the period after operation at which recurrence took place, and the site of recurrence in fifty-three consecutive cases of mammary carcinoma which had had no post-operative x-ray treatment. The period of recurrence in the 53 cases was as follows: 2 weeks in 1 case, 1 month in 5, 2 months in 4, 3 months in 7, 4 months in 2, 5 months in 1, 6 months in 2, 8 months in 2, 10 months in 1, 11 months in 2, 12 months in 7, 18 months in 3, 2 years in 2, 3 years in 9, 4 years in 2, and 5 years in 3. The site of recurrence is shown in the following table:

Site of Recurrence	First Year	Second and Third Year	Fourth and Fifth Year
Local	12	3	1
Supraclavicular	10	4	3
Axilla	1	—	—
Local and supraclavicular	6	3	—
Local and axilla	4	2	—
Supraclavicular and axilla	1	—	—
Spine	—	1	—
Thorax	—	1	1

The prevailing surgical practice was to regard supraclavicular involvement as a contraindication to operation, but it was apparent from the figures given that in the first-year recurrences there was apparently no clinical manifestation of supraclavicular involvement at the time of the operation, nor was there any evidence of it in the cases which occurred within three years. It was reasonable to suppose that the earlier the recurrence the more malignant was the character of the disease. It might be contended that all the cases in this series were of a very malignant type, and therefore had surgical risks, nevertheless, they indicated the advanced and almost hopeless stage in which the average patient with recurrent mammary carcinoma came to the radiologist for treatment, they showed also how essential it was always to include the supraclavicular space in prophylactic treatment as well as the pectoral region and the axilla. Such treatment was started usually in the second or third week, and most of the cases were treated according to the older methods, but during the past three years high-voltage rays had been employed. Time was too short and cases too few to compare the results of the newer with the older technique, but his impression was that for the prophylactic treatment of mammary carcinoma massive doses of highly penetrating rays were not only unnecessary but harmful, he believed, as Wintz had stated, that by their injurious effects on the healthy tissues they helped rather than hindered the recurrence of the disease. For precise measurements and accurate dosage on the surface and in the depths of the tissues the newer technique had obvious advantages, but for the prophylactic treatment of mammary cancer he considered that the rays produced by 135 to 155 kilovolts were the most effective. Of fifty patients who had prophylactic treatment seven were known definitely to have had recurrences, and of these seven one died within one year, four in the second year, one was doing badly from a deep-seated recurrence after five years, and one had recurrence after eight years which responded to further treatment, but she died later from the disease. In eleven cases the result was unknown, and thirty-two were known to be alive and free from recurrence after the number of years shown in the following table:

Years	1	2	3	4	5	6	7	8	9	10	11
Cases	1	5	4	4	6	3	2	3	2	1	1

The radiologist should have more information than was sometimes forthcoming about the histology of the cases he treated, for there was much evidence to suggest that there might be an optimum quality and quantity of radiation capable of producing a maximum inhibitory or lethal effect on a particular type of neoplastic cell. It was mainly along biological lines that future researches must extend, and the first endeavour should be to discover the relationship which existed between the quality of the radiation employed and the biological effects which were produced not only in the particular type of neoplastic cell, but also in the normal cells surrounding it.

Dr W M LEVITT (London) said that Dr Finzi had asked him to report on the histological examination of these cases after intensive radiation had been applied. Four patients had been investigated histologically, they had received intensified treatment by a method which gave them the full tolerance dose for about a fortnight. The histological examination was made about three months after the radiation. In one case it was found that there had been a most remarkable decrease in the number of malignant cells, and that there was a complete absence of mitosis in the cells which remained. In two cases there was very little decrease in the frequency of the malignant cells, but a complete absence of mitosis, and in the fourth case apparently there was no change in the character of the malignant cell. The obvious question related to the essential element in the malignancy of a tumour, was it the presence of a mitosis or some other characteristic? It was impossible to say. In one of these cases the tumour on removal had been cut right through, and what appeared to be malignant tissue had been left behind, but without mitosis, and the portion of tissue which had been cut through nine months before had not continued to grow. In connexion with the pre-operative treatment of malignant

disease, Dr Levitt suggested that local excision after irradiation might give a more satisfactory result. With regard to post-operative irradiation, if it was agreed that the selective sensitiveness of the carcinoma cells over the normal cells was proportional to their vital activity, then post-operative irradiation for prophylactic purposes was contraindicated altogether because any malignant cells which were left after complete operation were in a sort of hibernating condition. They did not commence to grow for quite a time afterwards perhaps as long as two or three years. In the bulk of cases he thought that pre-operative radiation was preferable to post-operative.

Dr R. F. ROBERTS (Liverpool) said that the treatment of malignant disease was one of the most depressing occupations anyone could undertake. In any large hospital the x-ray department was the dumping ground for all the surgical inoperabilities. It might be hoped that life was being lengthened, but it was a question whether it was not rather a case of prolonging death. No one could foretell exactly what response would follow from treatment. It was most disappointing when good curative or perfect prophylactic results followed operation that the patient should die after twelve or eighteen months from secondaries. The speaker thought that the secondaries must have been present from the time of the operation. The question of voltage was a very difficult one but he thought that Professor Haves had hit the nail on the head when he stated that for each type of malignant disease there was an optimum voltage, some cases responded best to high voltage and others to medium. The type of treatment had to be gauged by the general condition of the patient. In Liverpool a good deal had been done in the treatment of malignant disease by injections of lead and in the treatment of several of those cases subsequently by x-rays he had found that the lead injections appeared to assist the x-ray action the patients doing better than those who were subjected to x-rays without having had the lead treatment, there was a more intense secondary radiation.

The PRESIDENT (Dr Woodburn Morrison) asked what it was they were attempting to do when they irradiated breast carcinoma. If they were trying to destroy every individual cell in the breast they were committed to what was physically an impossibility. This could be easily demonstrated from the standpoint of pure physics. It would be found that calcification had taken place in some areas approximating quite unchanged cancer cells. From the physical point of view they could never accomplish in that way the pure destruction of a breast carcinoma. Dr Barclay had mentioned two patients, one of whom treated with deep therapy, had improved at first but died within six months and the other, treated superficially had lived much longer but his comparisons were not complete. He should have taken an untreated patient and observed how long life lasted. He wondered what would be the general average duration of life if a case of cancer were left entirely alone and how it would compare with the duration in cases in which operative followed by radiological treatment had been applied.

Dr FINEZ in reply, said that he believed it to be correct that every tumour had an optimum wave-length at which the treatment would do more harm to the carcinoma with less harm to the surrounding tissues than at any other wave-length. So far as he had gone it seemed to him that with the pushing up of the voltage better results were obtained in carcinoma and he still thought the optimum wave-length had not been reached because it was at present above the range which tubes would stand. Dr Barclay had suggested that the immediate results were good and the ultimate results bad the speaker thought that this was simply because the right technique had not yet been worked out. He denied that he was an indiscriminating optimist with regard to radiant treatment of breast cancer. He was an optimist in the case of localized breast carcinoma but the trouble was that they did not get cases like that to treat. In the cases described in his paper as having been treated with radium needles the results had been so satisfactory that at present the surgeon had refused to remove the breast because he could not feel

anything at all. Thus there could be no actual proof that in these cases the carcinoma cells had disappeared, but it was known that in the cervix every carcinoma cell could be made to disappear, that had been shown by others, using either radium or x-rays. He rather thought that that was the objective in breast carcinoma. As to massive doses for prophylaxis, he would retain his view, he believed in the hibernating cell, and that it was ready to grow. Dr Roberts had asked whether any good at all was being done but the older radiologists had seen patients who had remained well for five to ten years after treatment. He regarded the skin erythema as necessary because the dose which produced it was about the optimum for eradicating carcinomatous disease—he would not use the term “carcinomatous cells.” Some had maintained that carcinoma started as a generalized disease with a localized manifestation, Dr Finez did not believe that the disease originated in the blood or tissues generally, but that it started locally and subsequently became general otherwise, how could any disease at all be treated? He did not now get burns in the lung, because he had improved his technique. The goal of their attempts was to destroy all evidence of disease and so to treat the patient that no carcinoma cells would develop. It was possible that there might remain encysted hibernating carcinoma cells in the tissues, but so long as these did not develop it was well.

#### The Section of Radiology

At the conclusion of the meeting Dr L. A. Rowden (Leeds) made a protest against the confinement of the Section proceedings to one day only of the Annual Meeting, Dr A. E. Barclay associated himself with the protest, which the President of the Section promised should be conveyed to headquarters.

### MEDICAL, SURGICAL, OBSTETRICAL

#### CHRONIC FIBROUS EPILOITIS

THE publication by Mr R. Charles B. Munnell in your issue of June 11th (p. 1051) of his article on chronic fibrous epiloitis prompts me to record a case which presents many similar features.

A Chinese boy aged 10 was brought to me with symptoms of intestinal obstruction of three days duration. A large hard tender mass occupied the lower portion of the abdomen and extended from just above the umbilicus to the symphysis pubis.

The abdomen was explored by a right paramedian incision below the umbilicus. On opening the peritoneal cavity a dense tough membrane was found spread out in front of the abdominal viscera in a manner very similar to that described by Mr Munnell. This membrane was divided in the line of the peritoneal incision thus exposing the intestine. About two feet of small bowel were found to be gangrenous. Strong septa similar to suture to the membrane lying in front of the viscera passed backwards from it to the posterior abdominal wall thus dividing the abdominal cavity into a series of loculi and binding down and constricting the intestines. One of these septa had by obstructing the upper part of the ileum resulted in the gangrenous condition of the two feet of gut immediately below it. The septa and adhesions were divided sufficiently to free healthy bowel above and below the gangrenous portion preparatory to resection. At this point however the patient suddenly collapsed. A Pauls tube was inserted into the ileum proximal to the gangrenous portion and the patient was returned to the ward. Subcutaneous saline injection and the administration of glucose solution by the mouth and rectum resulted in so great an improvement that although by no means optimistic as to the chances of ultimate recovery I opened the abdomen again through the original incision on the third day following the first operation. It was found that the gangrenous portion of intestine had walled itself off from the rest of the abdominal cavity occupying a loculus of which the wall were largely formed by the adventitious membrane. The afferent and efferent healthy gut passed through the wall of this loculus to join with the gangrenous portion. The gangrenous intestine was resected the cut ends closed and side-to-side anastomosis was performed. Unfortunately however the extensive nature of the reaction proved too much for the patient in his debilitated condition and he died a short time after the completion of the operation.

Microscopical examination of a piece of membrane removed for section showed that it was composed of fibrous tissue upon which were superimposed the changes of acute inflammation. These changes which were secondary to the gangrenous condition of the intestine prevented any conclusions being reached as to the intimate structure of the fibrous membrane. The thickness of the membrane was approximately 1½ mm.

I think that the points of similarity between this case and that described by Mr. Munnell are sufficient to allow of their being considered as examples of the same pathological condition. In both there was present an adventitious membrane of similar characteristics, specialized portions of which were causing intestinal obstruction. It is perhaps suggestive that Mr. Munnell's patient, a European, should previously have suffered from bowel disease of a type very prevalent in the tropics.

#### DEATH AFTER ANAESTHESIA STATUS LYMPHATICUS

The following case, having some instinctive and extraordinary features, is, I think, worth recording.

A boy, aged 7, with well marked signs and symptoms of enlarged tonsils and adenoids was operated upon. He had the usual pre-operative preparation—namely, an aperient the night before and no food before operation. Anaesthesia was induced with a mixture of C and L (1/3) followed by pure ether, and was not remarkable in any way; the operation was successfully performed and there was no excessive haemorrhage. The patient had sufficiently recovered from the anaesthesia to cry out after the operation was concluded, and he afterwards sat up and talked to the nurse in charge. An hour after operation he suddenly turned a "nasty" colour, and when seen, immediately, by the house surgeon was rather of a blotchy purple blue but not generally cyanosed. He was pulseless and respiration had ceased. The usual remedies were tried—namely, artificial respiration, camphor oil, etc., cardiac massage, intracardiac and adrenalin injections were not used—without any response.

**Autopsy**—The body was of average size and conformation and of average weight. It showed, generally, a blotchy purple discoloration, very much like ordinary *post mortem* staining. The heart was empty, the lungs were not congested and were well aerated. There was a small amount of blood-stained fluid in the trachea, but no clot. No sign of embolism was noted. The liver appeared normal. There were no petechiae anywhere. The thymus, triangular in shape, covered the palm of an average hand ( $2\frac{1}{2} \times 2\frac{1}{2} \times 3\frac{1}{2}$  in). There was general enlargement of mesenteric glands, several being the size of an average walnut. The cervical glands were appreciably enlarged, but not matted or showing obvious signs of inflammation. The cause of death was given as "status lymphaticus."

The length of time before death after anaesthesia, and the lack of incident in the induction of anaesthesia, seem so extraordinary as to merit record, and the whole sequence of events, particularly the sudden and simultaneous cessation of all the vital functions, suggest the cause as being a vagotonic action due to hypersecretion of the thymus gland.

#### CHOLECYSTITIS WITH ASSOCIATED PANCREATITIS

The following details of a case in which cholecystitis was associated with pancreatitis seem to be worthy of record.

A married woman, aged 58, first attended as an out-patient in December, 1926, with a history of recurrent attacks of pain and tenderness in the right hypochondrium accompanied by vomiting, jaundice, and clay-coloured stools; she complained of flatulent dyspepsia aggravated by taking meat. These attacks had been intermittent for a period of five years, during which time glycosuria had coincided with the abdominal pain disappearing in the intervals. She had had dietetic treatment but no insulin.

On admission to hospital on April 4th, 1927, in addition to the preceding signs and symptoms, she was extremely tender over the gall bladder and there was slight jaundice. She weighed 8 st 5 lb. The urine contained 26 per cent of sugar and gave a faintly positive reaction with ferric chloride. There was hyperglycaemia, the actual figures of which unfortunately cannot be traced. A diagnosis of cholecystitis with associated pancreatitis was made, and it was decided to operate as soon as the urine could be rendered sugar free, as administered in doses of 25 units twice daily.

On May 2nd Mr. C. performed the operation, which was small and shrunken and contained a few faceted stones; there was definite pancreatitis. The wound healed by first intention, and three weeks later the patient was discharged on a slightly modified diet and twelve units of insulin twice daily.

Three months after the operation she was perfectly well, taking an unrestricted diet, and had increased 2 st in weight; there was no acidosis, and only an occasional trace of sugar in the urine.

The glycosuria in this case was apparently due to pancreatitis secondary to chronic inflammation of the biliary tract, and, although of five years' duration, cleared up after cholecystectomy.

I am indebted to Dr. Carey Coombs and Mr. Clifford Moore for permission to publish the notes of this case.

## Reports of Societies.

### SURGERY IN THE XVIII<sup>TH</sup> AND EARLY NINETEENTH CENTURIES

The first meeting of the 155th session of the Medical Society of London was held on October 10th, when Sir HUMPHRY RORTSTON relinquished the chair and inducted into it the new President, Mr. HERBERT W. CARSON.

Mr. Carson took as the subject of his address from the chair "Surgery in the early days of the Medical Society of London." He began with a sketch of the troubled political and social conditions of the last quarter of the eighteenth century, and said that during the first forty years or so of the Society's existence (from 1773 until Waterloo) England was in a state either of war or of social unrest which seriously affected all scientific pursuits, surgery included. The French Revolution was stated to have put back the progress of surgery in France so materially that France as a consequence lost the premier place in surgery, which before the revolution it had held. An interesting feature of surgical life at this time was the visits paid by surgeons to other countries. Not only did surgeons visit their colleagues abroad, but they expressed very frank opinions on what they saw. Cheselden (1688-1752), who was probably the best known surgeon in Europe in his day, received a deputation from Paris who had come to watch his operation of lateral lithotomy. Benjamin Bell of Edinburgh went on a tour in 1771, for which he asked his father for £150, stating that if he had intended to confine himself to medicine he would have been content to stay in Edinburgh, but as he was going to take up surgery a visit to London and Paris was essential. Another traveller was Astley Cooper, who in early life went to France, Italy, and Germany, and Abernethy at about the same time took a similar tour. Roux, the great French surgeon, in a book containing his observations on surgery in London, could not give greater praise to Charles Bell than to say that he "operated in the French manner." John Cross, visiting Paris in 1815, had many appreciative things to say of French surgeons. He watched Dupuytren operate on strangulated hernia, the operation taking place in the middle of the night, in a crowded ward, where the surgeon was surrounded by a press of students holding candles.

With the increase in the number of hospitals in London as the eighteenth century advanced more facilities were available for students, but teaching made slow progress. Even in 1816 Roux, comparing the opportunities for students in London and in Paris, said that in London the students gave considerable sums for liberty to frequent the hospitals. None of the courses in London was gratuitous even to those of the students who had the right of frequenting the hospitals where the courses were given, and Roux considered that the College in London was not to be compared with the corresponding Faculty in Paris. The museum in London, he said, was less a museum of anatomy than a collection of natural history, or it all events contained a collection of private classes. William Hunter, the surgeons arranged for private classes. William Hunter had founded his school of anatomy in 1770, John Hunter had his own school, and Hewson also founded a very successful school.

In trying to form a picture of the surgical work of the period it must be remembered that the surgeons suffered from two great handicaps—the absence of anaesthetics, and the absence of means for preventing sepsis. It followed that the scope of operations was limited by the speed factor, and that the great majority of the operations done to-day would have been impossible, not only because of the need for haste, but because of the inevitable infection. Some attempt was made, by compressing the sciatic and cranial nerves by means of a clamp, to numb sensation for an amputation, but this was given up. There were long arguments as to the right time to amputate. On the whole, surgeons were agreed that to amputate in spreading gangrene was fatal. Lithotomy was a great test of the surgeon's skill, and in most of the books of the period the operation was described in the minutest detail. Operations

for hernia were limited to reduction of strangulation. Pott in 1769 referred to "rupture doctors" as "murderers who ought to be hanged." Surgeons at this time did their own eye work. Not until the foundation of Moorfields in 1810 did specialization arise and thus specialization did not plea a Roux who said that it tended to consolidate what ought to be prevented—the separation of ocular from general surgery. Abdominal surgery until the nineteenth century was practically non-existent, except in the treatment of perforating wounds nothing was done. Hunter discussed the possibility of washing out the abdomen in peritonitis but never did it.

Mr Carson concluded his survey by quoting Sir William Ferguson who stated that about 1825 there was a period of calm such as there had not been for many years, and such as a later generation of surgeons had never seen. There was nothing new in British surgery, and little from abroad to attract attention. Nevertheless the scientific method was creeping into teaching, and for this development the first credit was due to John Hunter the bicentenary of whose birth would be celebrated in February of next year.

### PITUITARY DISEASE

At a meeting of the Manchester Medical Society on October 5th, with the President Dr J. Gray Clegg, in the chair, Dr CORNOR HOLMES gave an address on pituitary tumours.

He said that recent investigations went to show that many of the functions which had been attributed to the pituitary belonged to the nervous structures in the base of the brain especially in the hypothalamus. At present the only function that could with certainty be ascribed to the anterior lobe of the pituitary was an influence on growth, but it probably also controlled the development and activity of the sexual organs. Though extracts of posterior lobe had obvious effects when administered by injection its normal function was still unknown. The clinical symptoms of pituitary disease could however be still most satisfactorily divided into those attributed to an overfunction of the gland or rather of its anterior lobe and those resulting from its destruction or deficient activity. The chief symptoms of hyperpituitarism were acromegaly when the disease commenced after adolescence and gigantism, with which certain features of acromegaly or of hypopituitarism were often associated, when it began before normal growth was completed. The symptoms of hypopituitarism were more common and more varied. Dwarfism, usually associated with underdevelopment of the sexual organs and absence of the secondary sexual characters, resulted from destructive lesions of the gland before the age of puberty. It was usually due to extracranial tumours and other conditions that compressed the pituitary, for adenomata of the gland were rare at this age. Metaplastic adenomata developing after puberty produced Frohlich's syndrome or dystrophia adiposo-genitalis which was characterized by obesity, absence or regression of sexual development and of the secondary sexual characters, disturbances in carbohydrate metabolism, and frequently somnolence and polyuria. In addition to these symptoms, which were usually regarded as a direct result of the pituitary disease, other symptoms due to the pressure of the tumour on neighbouring structures were often present. At first the intracranial tension and later the increase of general intracranial pressure produced headache and occasionally vomiting while the compression of one hemisphere or of the cerebral peduncle might give rise to a hemiplegia. More characteristic symptoms were due to compression of the usual paths, which produced more or less characteristic defects in the visual fields, the type of which depended on where the pressure acted. When the chiasma was situated posteriorly one optic nerve generally suffered first so that unilateral blindness resulted, this was usually followed by a temporal hemianopia in the other eye when the tumour extended back to the chiasma. When the chiasma was first involved an irregular bitemporal hemianopia was found while the loss was mainly of the homonymous hemianopia type when the tumour compressed one optic tract. One early and frequent feature of the

visual defects, which was often forgotten, was the occurrence of scotomata, either central, when the optic nerve was compressed or more commonly paracentral in the temporal fields. The ocular nerves were frequently involved too, causing squint and diplopia. At present the most reliable treatment of pituitary tumours was operation, which had become a moderately safe procedure in skilled hands but good results had been obtained by radiological treatment, and it seemed that further development of this method might be expected. Glandular treatment, either to control the growth of the tumour or to relieve the symptoms of deficiency, had rarely given satisfactory results, but recent experimental investigations gave promise of greater success in the future.

### ELECTRO-CARDIOGRAPHY

At a meeting of the Brighton and Sussex Medical-Chirurgical Society on October 6th Dr DONALD HALL delivered his presidential address, entitled "Some help obtained from electro-cardiography."

Dr Hall's address was based on the examination in private practice of 419 patients during a period of 3½ years, and a short description was given of the method of examination and the normal electro-cardiogram. The speaker said that this method of examination supplemented but did not supplant ordinary clinical methods and no claim was made that electro-cardiography uttered the final word in diagnosis. Information regarding disorders of rhythm was given equally well or better by the electro-cardiogram than by the polygraph and in the case of the myocardium the polygraph was silent. In graphic methods the electro-cardiogram had superseded the polygraph in all pathological conditions except pulsus alternans, in which the sphygmograph was the more reliable. The various types of cardiac irregularities were demonstrated by lantern slides of electro-cardiograms and it was shown that the differential diagnosis of all these varieties could be obtained with absolute precision. One woman, aged 26 consequent upon the diagnosis of "heart strain" had assumed an invalid's life but the electro-cardiogram had disclosed a striking example of sinus irregularity, it was evident that the original diagnosis had been incorrect and upon it by suggestion, followed the patient's illness, which yielded to appropriate treatment. This was the only form of cardiac irregularity which was purely physiological. While premature beats were in many cases of but minor importance each case had to be considered on its merits. In general terms auricular and junctional premature beats were more frequently due to extrinsic causes, and in many instances the patient was unaware of their presence, while the ventricular premature beats were intrinsic in origin and the patient was usually cognisant of them. At times multiple premature ventricular beats might be the main cause of the patient's subjective symptoms particularly of giddiness and faintness, these symptoms disappeared on restoration of the normal rhythm. Simultaneous electro-cardiograms and pulse tracings demonstrated that, although the premature beats gave large complexes in the electro-cardiogram they were dynamically but feeble contractions, and thus while "extra-systole" was a misnomer, the term "dropped beat" was often correct so far as the pulse at the wrist was concerned. Dr Hall then discussed the probability of the QRS complex being able to give information otherwise unobtainable of the state of the myocardium. Electro-cardiograms were shown of two patients who were known to have had auricular fibrillation for fifteen years. In both of them the QRS was of normal outline in one the T wave was unchanged but in the other it showed the negativity of digitalis control. Slides were also shown of fibrillation before and after treatment by quinidine. Dr Hall explained the essential difference in the treatment of auricular fibrillation by these two drugs and also criticized the indiscriminate use of digitalis in cardiac affections, whether functional or organic. Observation of alteration in the ventricular complexes had given really important information sometimes where clinical evidence was but scanty or had been absent. Sixteen instances of right bundle branch block had been met with in the series the lesion affecting the left division in

three, and the right in thirteen cases. In his hospital practice the lesion of the right division had also been more numerous. In the series under review there had been thirty-five patients in whom the T wave was negative in Lead I or Lead II or in both. Three cases were untraced, but of the remaining thirty-two patients, sixteen were alive and sixteen were dead. Thus T negativity he had found relatively frequent in cases of angina pectoris, and examination by the electro-cardiograph had proved useful in strengthening the medical attendant's hand in the treatment of refractory patients. Slides were shown of heart-block, complete and partial, of the former one instance had been met with in a woman of 25, in whom the block seemed to be an isolated lesion. When young women complained of such symptoms as pain, faintness, palpitation, and shortness of breath, and on examination yielded little or nothing in the way of physical signs, and mitral stenosis could be excluded, it was safe to assume that the chest pain, which typically was submammillary and not retrosternal, was not of cardiac origin. A demonstration was given of the large P wave met with in mitral stenosis, but it was emphasized that with this one exception the electro-cardiogram was not concerned with cardiac murmurs. Middle-aged people, particularly men, were the most difficult cases of all, help was often obtained from the blood pressure and from the urine, but in a residue information could only proceed from an electro-cardiographic examination.

#### JAMES MACKENZIE INSTITUTE

This winter course of lectures at the James Mackenzie Institute for Clinical Research, St. Andrews, was opened with an introductory address by the honorary director, Dr. A. MITCHELL RIMSY, on the ocular manifestations of gastro-intestinal disorder. He pointed out that in gastro-intestinal diseases the causal relationship between the general disorder and the ocular symptoms was not nearly so direct and intimate as it was in the case of cerebral, renal, or circulatory affections, but that in an indirect way, through the agency of micro-organisms and of bacterial or biochemical toxins, gastro-intestinal disturbance played an important part in causing or in aggravating diseases of the eye. Attention was drawn to the reflex disturbances in the eye caused by dental caries or septic tonsils, which were also mentioned as the cause of acute or of chronic inflammation of the eyeball. A careful distinction was drawn between chronic intestinal auto-infection and chronic intestinal auto-intoxication, and in this connexion reference was made to the work of Desgeorges. Disordered metabolism was regarded as the underlying cause not only of inflammation of the nasal tract but also of acute glaucoma and of toxic amblyopia, and the influence of persistent constipation on the occurrence of intra-ocular hemorrhage in young adults was fully discussed. The attention of the general practitioner was directed to the possibility of atrophy of the optic nerve following severe haematemesis. The retinal ischaemia was regarded as a favourable condition for the action of a toxic or other infective agent, whose existence may be assumed although it did not admit of strict scientific proof. The lecturer concluded with a description of a group of eezematosus affections of the eye associated with disordered carbohydrate metabolism, and said that in the treatment of these conditions it was necessary to pay special attention to the diet, and also to take means to promote free elimination of the metabolic toxins which had accumulated in the blood.

Dr. SOUTER, in opening the discussion, referred to the wide experience of ophthalmology and of general medicine that Dr. Rimsy could draw upon. Dr. Souter touched on several of the points raised in the address and gave a short summary of those varied gastro-intestinal disorders, functional, organic, and toxic, in which eye features were likely to be met with, illustrating his remarks by reference to personal experience in several instances, special emphasis being laid on the help obtainable from an examination of the eyes in cases of unsuspected lactic affections.

## Reviews.

### ANGINA PECTORIS SURGICAL TREATMENT

In an elaborate work on angina pectoris Professor DANIELOPOLU expounds the rationale of the surgical treatment of the disease. The book, however, is not confined to that topic, but forms a complete treatise on the subject of angina pectoris, its etiology, symptoms, and pathogenesis, and the pathological anatomy is considered at great length. With regard to surgical treatment, the author states that the first suggestion of sympathectomy was a remark of François Franck's at the Académie de Médecine in 1899. "This new idea of acute sensibility transmitted by the cervico-sympathetic suggests the possibility of practising its resection in angina pectoris." The first operation of the kind was performed by Jonnesco and Gomoin in 1916, but the results being by no means encouraging, Jonnesco inclined to the opinion that the suppression of the angular attacks required division, not of the sensory fibres proceeding from the heart, but of the efferent fibres to the heart passing from the bulb and spinal centres, which would include the accelerator nerves and some of the coronary vasomotors. The attacks being regarded as due to a reflex from the heart, the object was to cut the afferent (Franck) or the efferent (Jonnesco) limb of the arc. Other operators endeavoured merely to relieve pain by the free division of the sensory fibres, without regard to the reflexes, the results were not of a kind to encourage a continuance of the practice.

Danielopolu's contribution to the subject consisted in the propounding of a theory of the pathogenesis of angular attacks, based on his own and others' experience, and, secondly, in defining the limits of safety in operating in accordance with the theory—a problem mainly of ascertaining the precise anatomical routes followed by the nervous impulses passing to and from the heart. His theory is that owing to defective blood supply (for example, from coronary disease) fatigue products accumulate in the heart when they reach a certain amount they irritate the sensory nerves, and these results not only pain, but also reflex stimulation which he considers to be predominantly pressor (that is, raised blood pressure, acceleration of the rhythm, increased force of contraction, and probably coronary vaso-constriction), the diminution of the heart is exaggerated by these pressor effects, the sensory nerves become still more irritated, and thus a vicious circle ("reflex pressor circle") is established, which culminates in the angular attack. The author contends that the proper treatment for this condition is to suppress the pressor circle by intercepting as many of the cardio-vortic sensory fibres as possible while preserving the efferent fibres passing to the heart from the medulla and upper part of the cord, since interference with the latter would be dangerous to the patient by destroying the pressor mechanism altogether. A large part of the book is devoted to a description of the nervous mechanism of the heart and to tracing the routes of the various impulses passing to and from it. From a minute investigation of the existing evidence on the subject—anatomical, physiological, pathological, and that derived from comparative anatomy and from incidental observations in the course of operations on the human subject—the author concludes that some of the sensory fibres pass along the inferior cardiac sympathetic nerves to the stellate ganglion, thence down the sympathetic trunk to the ram communicans of the second, third, and fourth dorsal spinal nerves, and that the pressor fibres descending from the medulla traverse the same route to the heart. These structures, therefore, it is dangerous to touch. But a number of other sensory fibres, avoiding this route, pass by way of the stellate ganglion, and in the upper and middle cardiac nerves of the sympathetic and branches of the vagus, these can be divided without endangering the pressor mechanism. Danielopolu therefore advised an operation in two stages: first the division of the sympathetic trunk above the

inferior cervical ganglion, of the upper and middle cardiac nerves of the sympathetic, of the vagal branches descending in the thorax of the rami communicantes of the last three cervical and first dorsal nerves, and of the vertebral nerve running from the inferior cervical ganglion of the sympathetic. In the second operation the trunk of the cervical sympathetic is removed above the inferior cervical ganglion. Thirteen cases in which the operation had been carried out are described, and appear to justify the author's opinion as to the advantages to be anticipated from it.

Danielopola's book is a genuine contribution to the subject: it is a serious attempt to discover guiding principles in operating for triguna, to replace the empirical division of this or that nerve in the hope that some benefit will accrue.

### CLINICAL PHYSIOLOGY

Is an interesting volume not too long entitled *Clinical Physiology in Relation to Modern Diagnosis and Treatment*, Professor McDOWELL has brought together a large proportion of those facets of the science of physiology which are particularly relevant to an understanding of the manifestations of disordered function—the concern of the art of medicine. He takes a wide view, for he devotes chapters not only to topics commonly treated in textbooks of physiology, but also, for example, to "Life as a clinical entity," "Consciousness." Some physiological aspects of psychology and psychotherapeutics, and "Protection against disease." But it is not to the choice of material, but to its disjunctive treatment that we look for characteristics justifying the recognition of a definite subject—clinical physiology. With the sciences of medicine, pathology and physiology well established it may perhaps be questioned whether such an addition to the ordinary classification is profitable. Professor HALLINGTON in a short introduction, expresses the opinion that those who give instruction in physiology cannot teach what will later be of use to the medical student in the wards and that clinical teachers are not always capable of inculcating physiological knowledge if it deals with recent discoveries and views. This book is intended to remove these difficulties.

The immense number and variety of conditions of medical interest discussed in so short a volume entail a mode of approach which is inevitably sketchy. The physiological "explanations" of symptoms, for example are in terms of conclusions reached by physiologists concerning the mechanisms they have studied. The further step of relating these hypotheses to the experimental facts they summarize is rarely attempted, since a knowledge of textbook physiology is taken for granted in the readers to whom the book is addressed—senior medical students and practitioners. If the wisdom of undue emphasis on incomplete correlations of this kind is to be questioned it would be partly because the student already has opportunities of hearing just such sketchy presentations at the bedside, and partly because facile judgements may be based on explanations in which the standards of evidence are not sound to the detriment of the progress of medicine and of the repute of physiology. Is there a class of readers for example that needs to be told what are the Ewald and Rehfuss methods of investigating gastric contents and that can usefully apply a discussion of the mechanism of duodenal regurgitation described by Bolton and Goodhart, without the further information here omitted as to the evidence on which the discovery rests? The omission of figures and curves from the text has saved space but has obscured crucial steps in some of the author's arguments.

The work, in spite of a good many misprints of some ambiguous phrases and a few notable omissions—as of Chvostek-Stokes respiration—is full of valuable material, which will enrich the medical experience of a reader who has not had recent opportunities of watching physiological developments.

*Clinical Physiology in Relation to Modern Diagnosis and Treatment* By P. McDOWELL, M.D., F.R.C.P. With an introduction by W. D. H. Hallington, M.D., F.R.C.P. F.R.S. London: E. Arnold, 1927. (Demy 8vo pp. xiii + 412 net.)

### VACCINE THERAPY

THE scope of LEONARD S. DEDMON'S *Bacterial Vaccines and their Position in Therapeutics* is well summarized in the preface: "No attempt has been made to review the literature of this vast subject."

I have attempted to place on record my direct personal observations, based on twenty years' experience of the vaccine treatment of acute and chronic bacterial infections. There is little doubt that many of the views and conclusions recorded in this short monograph on vaccine therapy will not be in agreement with the much too optimistic statements so frequently made on the subject. No one who has studied vaccine treatment seriously can question its value, but it is equally important to understand its limitations. The selection of cases suitable for vaccine treatment requires much experience, while the problem of dosage, which is different in every case, is still far from understood. In prophylaxis vaccine therapy has done great work. The book is divided into nine chapters, the first three dealing with the principles, production and standardization, the fourth with prophylactic inoculations, the fifth with acute generalized bacterial infections, and the others with infections of the genito-urinary system, of the gastro-intestinal system, of the mouth and respiratory system, and of skin, connective tissue, bones, and joints. The book should prove most helpful to all who are interested in the subject.

### TROPICAL MEDICINE

To the series of books published by Masson of Paris under the general title *Precis Medicines* there has been added a volume on tropical medicine, by Professor JOVEUX, now of Paris, making a companion volume to Brumpt's well known *Precis de Parasitologie*. It is divided into two parts: the first deals with diseases of the various systems and organs of the body, the second with tropical fevers. To the English reader such an arrangement whereby amoebic hepatitis and liver abscess are divorced from intestinal amoebiasis, will perhaps appear unsatisfactory. Agranulocytosis follows in sequence after the flagellate diarrhoeas. Familiarity with this plan is, however, soon gained and the subject matter is excellent. What shall and what shall not be included in a textbook of tropical medicine is a difficulty every author has to meet and the author, in his preface, quotes Manson as his guide.

If tropical diseases be meant diseases peculiar to and confined to the tropics then half a dozen pages might have sufficed for their description. If on the other hand the expression tropical diseases be held to include all diseases occurring in the tropics then the work would require to cover almost the entire range of medicine.

Joveux has therefore followed very much the lines of our own well known textbooks but there are certain differences. Systematic parasitology and bacteriology find no place in this volume, a departure which, for the English student of tropical medicine brought up on what may be called the "Manson tradition" must appear a retrogression. On the other hand the clinical descriptions are good in the main though perhaps greater clearness would have been attained had such diseases as malaria, trypanosomiasis and recurrent fever been described in separate paragraphs under the several varieties of parasite.

Alastrim, scurvy, Malta fever and trench fever are dealt with but not pellagra and it might have been well to have embodied some notes on syphilis, tuberculosis, and pneumonia as seen in native races.

The book on the whole is up to date but here and there is a failure to note recent work such as the treatment of malaria by plasmochin or the treatment of climatic bronchitis by the method advocated by Hanschell. It is interesting however to see references to the fever caused by the bites of amblyomma, to the epidemic jaundice of spirochaetal origin described by Blanchard at Brazzaville, and to the

*Bacterial Vaccines and their Position in Therapeutics* By LEONARD S. DEDMON, M.D., F.R.C.P. London: Modern Medicine Monographs. Edited by H. H. MacLachlan, M.D., D.Sc. London: Cassell and Co., Ltd., 1927. (Demy 8vo pp. vii + 271 net.)  
*Precis de Médecine des Tropiques* Par Ch. JOVEUX. Paris: Masson et Cie, 1927. (5 x 7 1/2 pp. 651. 130 figures. 60 fr. an majoration.)

condition called "halzoun" in Libia, due to the ingestion of goat's liver harbouring fasciola hepatica. The author also appears to accept a spirochaetal etiology for blackwater fever. Most of the illustrations reproduced from photographs are good, some others are poor.

It is always interesting to read a textbook in another language, but, while the present volume will prove of great value to those for whom it has been written, the English student will probably prefer the books with which he is already familiar.

### INJECTION TREATMENT OF VARICOSE VEINS

To those interested in the treatment of varices by the injection of sclerosing substances we can recommend a small book, *The Modern Treatment of Varices*,<sup>1</sup> a translation into English by Dr T. C. MERRILL of an essay by Dr Louis HUMBERT.

The author bases his recommendations on seven years' experience, the best method in his opinion is the injection of sodium salicylate into the veins. He follows this up by applying strapping, a procedure other surgeons have not considered necessary. Adhesive bands, consisting of strips of gauze smeared with Unna's paste, are applied from the root of the toes to the popliteal space. It prevents swelling of the limb, abolishes distension of the varices, and relieves congestion through the dehydrating properties of the glycerin present in the paste. The patient may continue his regular occupation with the strapping on. Ascending and descending injections are made, the latter are more commonly used. The manner of making the injections, the position of the patient, the disadvantages, contraindications, and the practical applications of the method are all described in detail.

To those who prefer the sodium salicylate injection this book should especially appeal.

### CRIMINAL PSYCHOLOGY

An important study of criminal psychology, entitled *The Psychology of Murder*,<sup>2</sup> by ANDREAS BJERR, Professor of Criminal Law at the University of Dorpat, has been translated from the Swedish with the idea of spreading in foreign countries a knowledge of Swedish legal methods. The work in the main is made up of a very detailed study of the life history of three murderers. The author claims that if the comparatively new subject of criminal psychology is to advance, it must be by personal observation and personal contact with individual examples of crime. Whilst believing that in the case of theft and of offences against public decency and morality it is possible to make out groups or types, Bjerr states that so far it has not been possible to do this where murder is concerned. The careful histories of the three criminals in this volume bear out this conclusion. There is nothing from which it would be possible to draw any generalizations. A very much larger series of investigations is necessary before the aim of the author to find types can be realized.

The method adopted by Bjerr is to throw as far as possible a clear light on the determining factors in the psychic development of the criminals from a period as far back in their childhood as he could reach to the day they committed their crime, and then to advance to psychic facts and processes of which the poisons under observation had either never been conscious themselves or of which they, at any rate, had lost recollection and which they would therefore deny if presented to them. The author does not claim that by this method he has reached any very decisive results, but he believes that in this way there is a possibility of piercing the psychic life of an individual and discovering what is or has been in his mind.

In the course of his investigations the author arrived at certain definite conclusions. He is firmly convinced that all attempts to explain the psychic life of criminals by assuming sexuality is the primary and determining

force in their lives is doomed to be either a superficial and often unworthy juggling with words, or else, by arbitrary and fundamentally misdirected surmises, to divorce investigation from reality. He has formed the definite opinion that conscious and unconscious deviations from normal sexual development, i.e., apart from certain forms of homosexuality, only symptoms or effects of deeper-seated psychic defects and are never primary causes of the growth of criminal qualities. He does not accept the popular view that the confessions of criminals are either the result of remorse or a realization that further denial is useless. In the case of murderers he believes that without exception they confess because they expect to obtain some advantage or because they recognize the justice of their sentence. He is of opinion that the anthropological school of Lombroso may, as the result of further investigation, be justified in their view that there is an affinity between the lowest and most primitive races and criminals.

This study of criminal psychology reveals many interesting points in the mental outlook of the three convicted murderers and in the motives which led to their crimes. The author had hoped to continue his investigations, and possibly arrive at a stage when he could make a more definite pronouncement on the question of types or groups in the case of murderers. His early death has unfortunately precluded the realization of this wish. The work is well worth the study of all interested in criminal psychology.

### SIGHT AFTER MID-LIFE

As we have already had occasion to mention, the staff of the medical school of Harvard University give public lectures in medical subjects of general importance, and a number of them have been published under the general title "Harvard Health Talks." The fourteenth of the series is by Dr J. Herbert Warte, instructor in ophthalmology in the medical school. It is entitled *Saving Eyesight after Mid-Life*.<sup>3</sup> He begins with the statement that 55 per cent of cases of total blindness result from causes within the body, which operate silently at all before the fortieth year, but with increasing frequency as age advances. After a sketch of the processes of sight, he proceeds to the chief cause of the loss of sight in age—glaucoma. He states that in the United States it causes one-third of all blindness arising after the fortieth year. Yet this disease practically always yields to certain forms of treatment provided the patient receives the treatment early enough. He then shows how the circulation of the fluids within the eye is maintained and what tends to check the balance of the flow, producing that excessive pressure which is so injurious to the sensibility of the retina. Considering treatment, he urges that the drug method of controlling glaucoma is at best only a temporary expedient, and its exclusive use justified only in people so old that their expectation of life is less than the period of effective action of the drug. As de Wecker said, "If motile drugs have never cured a case of glaucoma, they have prevented many glaucoma patients from being cured." Next he shows how vascular changes induce cataract, and explains the risks of growths in the eye, not only to the eye but to the body generally.

He sums up thus: To save eyesight after mid-life, remember (1) That periodic examination by an oculist is necessary, because of the insidious onset of degenerative disease of the eyes. (2) That cataract may be part of a process, not limited to the crystalline lens, but heralding the presence of a more deep-seated and serious disease of the eye. (3) That blindness from glaucoma, which at present amounts to one-third of all blindness arising after mid-life, can usually be held in check if the patient will only co-operate with his oculist.

The little book is well done, and would be a useful gift to one worrying as to what course to take when the existence of glaucoma is known. We think the author might have made some note on the benefit which proper reading glasses bestow on old folk, but perhaps he thought that so well known as to be self-evident.

## NOTES ON BOOKS

PROFESSOR M. R. DRENNAN of the University of Capetown has published a small book of forty pages entitled *Short Course on Human Embryology* which will be found useful by teachers of that subject in this country and by students. It is the course which is given in the University to medical students and may be taken as a good example of the kind of course which may be introduced into the already somewhat crowded syllabus of anatomy. It has the special merit of presenting the complicated subject of human development in a manner that is at once very concise and yet readable and interesting and the material is arranged under headings following one another in a natural order of sequence which greatly facilitates the comprehension of the whole. The descriptions also are excellent—full of essential detail and free from redundancy. The student can use this small work as a stand-by and first textbook of the subject giving him a good grounding from which he may proceed to the study of larger and more detailed works. As a companion to the short course the author has published a pamphlet of sixteen pages of *Illustrations for a Short Course on Human Embryology*. This consists of photographs and diagrams designed to illustrate the descriptions. Figures of this kind are usually incorporated in the text but there is a certain advantage in having them separate and arranged in serial order so that the stages of development can also be followed pictorially apart from the text. The two booklets are published by the author from whom they may be obtained, the price for the two being 5s.

*Antigenotherapie de la Tuberculose* is an account by Drs. Nègre and Boquet of their researches at the Institut Pasteur for the production of an antigen for tuberculosis and of the results of its use in man and animals. The authors found that an extract in methyl alcohol of tubercle bacilli previously treated with acetone formed a very sensitive antigen of fixed stability. When freed from the methyl alcohol suspended in normal saline solution and injected into healthy animals the extract produced antibodies which were considerably increased if the extract was injected into animals infected with tuberculosis. In tuberculous guinea pigs and rabbits the evolution of the disease was retarded—it did not tend to become generalized, often it remained localized in a single organ and after a treatment of several months duration a process of sclerosis set in. Similarly in man many mucous glandular and osseous articular and peritoneal lesions retrogressed or disappeared entirely though in some cases the extract failed to act. Drs. Nègre and Boquet are not able to write with so much certainty about pulmonary cases but they state that several clinicians have observed improvement of the general health, a lowering of temperature, a diminution of sputum and an improvement in auscultatory signs. There is a preface to the book by Professor Calmette who is of opinion that antigenotherapy should take a place of greater and greater importance in the treatment of tuberculous diseases, especially if they are afebrile.

\* *Antigenotherapie de la Tuberculose*. Par L. Nègre et A. Boquet. Préface du Dr A. Calmette. Paris: Masson et Cie, 1927. (5) 1/2 x 7 1/2 pp. 158. 2 plates. 16 fr. sans majoration.

## PREPARATIONS AND APPLIANCES

## Maxillary Antrum Rasp

Mr. ARBAN EVANS, surgeon to the Ear, Nose and Throat Department of the Swansea General Hospital, has devised two rasp

forward and backward cutting respectively which he has found most useful for opening up the maxillary antrum beneath the inferior turbinate bone in cases of empyema. The first is a modification of Dr. Watson Williams's instrument for the intranasal operation on the frontal sinus. In both directions consideration has been given to the angles between the inner wall of the antrum and the anterior and posterior boundaries. The rasps, as shown in the illustration were made by Messrs. Mayer and Phelps, 59 New Cavendish Street, W.1 several years ago and Mr. Evans states that they have been used in a great number of cases with satisfactory results.

## A MEDICAL REVIEW OF SOVIET RUSSIA

## VI—WORK OF PAVLOV AND OTHER SCIENTISTS

BY

W. HORSLEY GANTT B.Sc. M.D. VIRGINIA

(Formerly Chief of the Medical Division of the American Relief Administration, Leningrad Unit)

## PART II—ORBELI, SPERANSKY, AND OTHER INVESTIGATORS

## ORBELI'S WORK ON THE SYMPATHETIC NERVOUS SYSTEM

THE work of Professor Orbeli is entirely independent of that of the Pavlov laboratory, but he is none of Pavlov's oldest pupils, and Professor Pavlov told me that he considered his work extremely important. A description of some of Orbeli's work was given in the *BRITISH MEDICAL JOURNAL* of September 20th 1924 (p. 533). He has been kind enough to give me a summary of all he has done since and to demonstrate his new work to me. The following account is founded on what I have seen and the written account Professor Orbeli has given me. Part of this has been published in Russian and part is as yet unpublished.

Langley supposed that the autonomic nervous system has no influence on skeletal muscle. Orbeli, in an article in the jubilee volume presented to Pavlov, says:

'In the last twelve to fourteen years this point of view about the sympathetic nervous system has been subject to doubt and revision. On the one hand the histological findings, in a series of motor end plates nerve endings of the second order, more delicate and finer plates connected with unmyelinated fibres indicated on the basis of regeneration experiments that they were sympathetic. On the other hand physiologists have recorded various experiments explaining the sympathetic innervation of skeletal muscle.'

A few years ago unaware of the anatomical experiments of Boeke and Aghdur and the accompanying physiological investigations I on the basis of a number of considerations suggested that the sympathetic nervous system is truly universal and must have a direct influence on skeletal muscle as on all other systems in the organism and that this effect might be expressed with such variations in the properties of muscle as first described by Pavlov and Gaskell for heart muscle and later described by Englemann under the terms bathmotropic, inotropic, dromotropic and tonotropic.

From experiments by Ginetzinsky on the frog Orbeli is led to conclude that the sympathetic nervous system has two antagonistic influences, and that a certain relation exists between the functional disturbances produced by irritation of the sympathetic and the chemical processes which underlie muscular rigidity. In poisoning with chloral hydrate, following stimulation of the sympathetic tonic contractions supervene, beginning after a long latent period, and continuing as an after effect. Apparently we have to do here with an easily reversible form of those changes which if of greater intensity lead to muscular rigour (Streloffi).

The electrical conductivity of resting muscle and muscle fatigued by tetanizing was compared by Lebedinsky. The recovery of the tetanized muscle was hastened by stimulation of the sympathetic. Tetanization lessened the resistance of the muscle to the electric current but in the majority of cases the stimulation of the sympathetic accelerated the return to the normal.

Orbeli and Fiedelholz have investigated the "pseudomotor" or "tonomotor" effect of the lingual nerve on the musculature of the tongue. Opposing explanations of this have been given by Van Rynerk and by Frank. The hypoglossal nerve was cut about two weeks previous to the experiment to give the fibres time to degenerate. By trying the effect of stimulation of the lingual nerve at various periods after its section, the pseudomotor and the vascular phenomena can be independently elicited. From this it may be concluded that the tonomotor and vasodilator effects are to be assigned to different nerve fibres. Adrenaline was injected intravenously to reinforce the action of the sympathetic on the tonomotor influence. In these experiments the effect of the lingual stimulation.

Part I of Section VI of this series was published in the *JOURNAL* of June 11th 1927 at page 1070.

was indisputably strengthened and was especially marked when the lingual fibres began to degenerate. The results obtained are in full agreement with the behaviour of the sympathetic in other forms of motor innervation.

Ginetzinsky, in Orbeli's laboratory, repeated the experiments of Elze on the frog, with certain modifications designed to give more definite results. Ginetzinsky eliminated the influence of the afferent nerves, and showed that the sympathetic alone was responsible for the effect. Both suprarenals were removed and the sympathetic chain was cut on one side. The muscles which had been deprived of the sympathetic innervation were more quickly exhausted and the height of the contraction was less.

In June, 1925, Dr Tonkikh reported from the Orbeli laboratory the effect upon spinal reflexes of experiments on the sympathetic. By stimulation of the lower end of the sympathetic trunk an inhibition or augmentation of the spinal reflexes was produced and paralysis followed. This was analogous to the ascending paralysis which Professor Pavlov had at first described as an accidental result of the operations, but which he later attributed to the presence of trophic nerves. He stated in 1920 that the existence of such trophic nerves had been proved only in the case of the heart, but that they might be supposed to exist for other organs, to exert a definite and final control over the metabolism and the mechanical processes occurring in the various tissues. It thus appears that the experimental work of Orbeli may give an actual foundation to the hypothesis of Professor Pavlov in regard to trophic innervation. Orbeli summarizes his work as follows:

"The sympathetic nervous system exerts a profound influence over the chemico-physical changes occurring in skeletal muscle, accompanied by a modification of its functional ability. These changes influence, it seems, the conditions of the motor end plate, call forth changes in the efficiency of the corresponding muscles, and form a sort of regulatory mechanism for the expenditure of muscle strength and govern the conduction of impulses by the motor nerves. From this point of view the sympathetic innervation of skeletal muscle is an adaptive innervation through which the functional ability of the muscle is determined."

#### OTHER NEW WORK OF ORBELI

Further experiments from Orbeli's laboratory show that the efferent sympathetic fibres have a direct influence on the central part of the spinal reflex arc. The work was carried out on completely bled frogs from which all the viscera and the heart had been removed.

After demonstrating the direct effect of the efferent sympathetic fibres on the central part of the reflex arc of spinal reflexes, there arose the question of a possible influence of the central part of the sympathetic system on the spinal reflexes. To solve this problem Tonkikh made an experiment by Setchinov's inhibition method—the stimulation of the optic thalamus with sodium chloride, on the assumption that the centre of the whole sympathetic system lies in the subthalamus region. Orbeli concludes from these experiments that in this case there is no direct reciprocity between different parts of the central nervous system, but that there is a regulating activity of one part of the central nervous system by others through the sympathetic.

Experiments of Ginetzinsky performed in an atmosphere of hydrogen prove that the effect provoked in skeletal muscle by stimulation of the sympathetic cannot be explained exclusively by the augmentation of the oxidation of the products of metabolism. Other experiments demonstrated that the effect of the sympathetic in skeletal muscle occurs in that place where the stimulus from the nervous tissue is transferred to the muscular—that is, in the peripheral apparatus of the motor nerve.

Experiments on dogs showed that when the left abdominal sympathetic trunk was resected the thresholds of stimulation on the two sides differed, thus lends support to the hypothesis of Orbeli that the sympathetic contains regulating fibres for the motor as well as for the sensory end apparatus.\*

#### CEREBRAL PATHOLOGY

Much interest has been aroused by the researches of Dr A. D. Speransky, formerly a surgeon, conducted in his own laboratory, as well as in Pavlov's. He produced an auto-neurotoxin giving rise to epileptic convulsions and death in dogs by freezing a small part of the brain. Immunization against the symptoms of freezing has been partly successful by freezing the brain gradually in increasing doses. If the frozen brain emulsion in a dying animal was injected subdurally in a healthy dog it could resist larger doses of freezing. Recently he has been concerned with the pathology of the cerebro-spinal fluid in encephalitis. He says (personal communication):

"In local disease of the nervous system a destruction of the brain substance occurs in the affected parts. The products of destruction are transported into the cerebro-spinal fluid and through it poison the brain. In such a way local disease becomes general, and to this mechanism is due the development of diffuse encephalitis."

"The greatest quantity of the cerebro-spinal fluid comes into relation with the brain substance in the region of the ventricles."

This is why subcortical destruction often occurs earlier than cortical. The structural changes in the brain and the clinical symptoms in all toxic encephalitis, as tetanus, hydrophobia, diphtheria, epidemic encephalitis, toxic encephalitis from freezing the brain cortex, have many things in common. In all of these the parts of the brain lying in the vicinity of the ventricles are affected, in all are observed changes in the cornu ammonis, in all there is an infiltration of the shallow parts of the brain substance near the ependyma. The internal brain substance in nearly all of these cases has an infiltration in a circle of cells, not around the blood vessels as was formerly supposed, but around their adventitious sheaths filled with cerebro-spinal fluid."

Speransky, during the summer of 1926, devised an operation to isolate for study small sections of the subarachnoid and subdural spaces without disturbing the rest, in a way somewhat analogous to that by which Pavlov isolated a miniature stomach for collection of the gastric secretion. His recent work with the cerebro-spinal fluid has led Speransky to form the following conclusions as to the haemato-encephalic barrier: its site is uncertain, but it is known that substances in the blood do not occur in the cerebro-spinal fluid. Although ordinarily it has a defensive action, in pathological conditions it may have an undesirable action. Thus some toxins, as that of tetanus, are not arrested by this barrier, but the antibodies and specific serums are. The toxins which reach the brain are fixed there and are not eliminated, but the antitoxins are quickly destroyed, and their return to the blood is prevented by this barrier. The introduction of specific antibodies in the subdural and subarachnoid spaces does not ensure penetration into the brain. His results with rabies, diphtheria, tetanus, dysentery, scarlatina, measles, and meningitis are as follows:

**Rabies**—Speransky says that rabies is a disease of the brain only, and can be treated by passive or active immunization. Ordinarily antirabic serum injected into the subarachnoid space cannot penetrate to the interior of the brain, but if hyperemia is produced artificially by removing all the cerebro-spinal fluid penetration begins. Under such conditions the action of the antirabic serum is specific—the same *in vivo* as *in vitro*, because it comes into contact with the virus. Subdural injection is efficacious clinically, whereas intravenous is not, because of the haemato-encephalic barrier. Speransky has overcome this obstacle by withdrawing cerebro-spinal fluid at the same time as the injection is made. He considers that the tons of the cranium and of the brain substance are complementary, and that the pressure in the latter is dependent upon the pressure of the surroundings. He was led to this view by observing that there was no bleeding during trephining if the cerebro-spinal fluid had been withdrawn, and that after removing a large amount of cerebro-spinal fluid the next portion, instead of being colourless, was yellow. Antirabic serum was injected into the ear veins of twenty rabbits, and then in ten of them 1 to 1.6 c.c. of cerebro-spinal fluid was removed by aspiration and reinjected several times before final removal. After one to two hours the brains of all twenty were inoculated with

\*For details of these last experiments see W. H. Gantt, Work of Pavlov's School, *Arch. of Neurology and Psychiatry*, Chicago, April 1927. For a full bibliography concerning the sympathetic and muscle tonus, consult Stanley Cobb, Review on the Tonus of Skeletal Muscle, *Physiological Reviews*, October 1926, p. 519.

the virus of rabies. Those in which the cerebro-spinal fluid had been removed remained healthy, while all the others developed rabies. This process of aspiration and re-injection I shall refer to as re-aspiration.

**Diphtheria**—Eighteen pairs of rabbits were injected with diphtheria toxin, and, after an hour, with antitoxin. The 18 controls died on the third day. In the other 18 the cerebro-spinal fluid was aspirated and re-injected five to ten minutes after the antitoxin. Five of these remained healthy, 11 outlived the controls by three to five days, and 2 died at the same time as the controls, but when the re-aspiration was done, not one hour, but forty-five minutes after the injection, all the animals survived.

**Tetanus**—Re-aspiration lengthened the life of the animals, but did not prevent death, owing as Speransky believes to the early fixation of the tetanus toxin in the brain. Six clinical cases of tetanus have been treated by re-aspiration. The antitetanus serum was introduced in five cases intraspinally after withdrawal of 40 to 110 ccm. of cerebro-spinal fluid, which amount can be aspirated under narcosis without unfavourable results. The operation was repeated after one to two hours and was done four or five times. Five of the cases recovered gradually, but in the sixth no fluid was obtained, and owing to this failure to produce hyperaemia by aspiration death occurred.

**Dysentery** also was treated by this method. In animals which had already developed diarrhoea and paralysis the best results were obtained by simultaneous injection in the blood and in the cerebro-spinal canal, in no case did intravenous injection alone produce a cure. Although the union of the dysenteric toxin with the brain substance does not appear to be so stable as that of other toxins, Speransky concludes that the penetration of the specific antibodies into the central nervous system is necessary for the serum to produce its curative action. He suggests also that the difference between the action *in vitro* and *in vivo* of many other serums (anticholera, etc.) is due to the failure of contact between virus and serum. Anti-diphtheria serum has nearly the same effect, whether it is introduced subcutaneously, intramuscularly or intravenously, because diphtheria toxin can destroy the barrier, it leaves the gate open" while all other toxins which pass this barrier "close the gate behind them," so that antibodies cannot enter.

**Scarlatina**—Eight grave cases were treated by aspirating 15 to 20 ccm. of cerebro-spinal fluid and injecting 4 to 10 ccm. of serum,\* five of these completely recovered (disappearance of fever, exanthem, and symptoms), in two there was an incomplete effect, and in one there was no effect. Injection of the same amount subcutaneously into the blood or muscles was without effect, although the use of 100 to 200 ccm. by these routes is effective. The best results were obtained by simultaneous introduction on both sides of the barrier.

**Meningitis**—Speransky's method of re-aspiration led, in four grave clinical cases of acute epidemic meningitis, to recovery commencing simultaneously with the procedure. Re-aspiration was repeated every two to four hours, and 10 to 20 ccm. of fluid was withdrawn.

Speransky holds that the appearance of "general" symptoms of a disease indicates penetration into the central nervous system, and that many local lesions are due to an affection of the corresponding parts of the central nervous system. The rapid oscillation of pressure caused by re-aspiration changes the circulation in the blood vessels of the brain to such an extent as to permit antibodies in the blood to pass through. Although Speransky has never seen any diaphoretic effects from the use of this method, he says that his clinical material is too small to draw a conclusion, and he cautions against its indiscriminate use, since it may be very dangerous to remove too much cerebro-spinal fluid in some cases.

#### PREVENTION OF NEURO-MUSCULAR FATIGUE

Professor A. A. Bogomoletz of the Second University of Moscow, who has made many contributions to contemporary

The Russian serum is considerably weaker than the product of Fatae Davis.

Russian pathology, recently called attention to the importance of the mesenchyme in determining constitutional types, a healthy reticulo-endothelial system is, he states, the best protection against cancer and this he has substantiated by preventing the development of experimental cancer through the use of a cyto-stimulant of the reticulo-endothelial system.

In 1925 he reported that neuro-muscular fatigue in horses can be lessened by the administration of sugar. This received practical confirmation during the Moscow races of 1926, when a horse which had always lagged behind was treated by Professor Bogomoletz, with the result that it won first place and the professor the prize of 30,000 roubles given by the Government for scientific research.

Chemical examinations of the blood of race-horses showed that the variations were constant in each individual. Three groups were distinguished: (1) those with normal content of blood sugar, (2) those with hyperglycaemia, (3) those with hypoglycaemia. The latter were found quickly to become fatigued, and to show slight hyperglycaemia after the race. The administration of 500 to 1,000 grams of sucrose daily increased the blood sugar, and simultaneously bettered the horses' racing time and diminished the subsequent fatigue. Professor Bogomoletz has informed me that in some horses which could not even finish the course he succeeded, by changing the diet on the basis of the blood analyses, in improving their general condition to such an extent that they often won first place. On the other hand, the administration of sugar to those of the first group often caused a reduction of the blood sugar, which is explained by Professor Bogomoletz as due to a probable interference with the function of the islands of Langerhans.

The amount of phosphorus in the blood after racing showed an increase parallel with the hyperglycaemia. It is possible, according to Bogomoletz, that we have here an automatic chemical regulation of the production and destruction of lactacidogen and that phosphoric acid ( $H_2PO_4$ ) quickens the breaking up of glycogen. It was found in large quantities in fatigued isolated muscle.

The increase in the concentration of  $H$ -ions and the reduction of those of  $Cr$  formerly observed in athletes was found also in horses during the races. Bogomoletz considers this to be an important factor in fatigue. The prevention of fatigue should have regard not only to the above facts, but also to the aeration of the blood before exercise by thorough ventilation and the administration of oxygen.

#### CANCER

Several methods of treating cancer have been tried in Russia since the revolution. Besides the Molotkov method, which has been published, and which consists in cutting the sympathetic nerves in the cancerous area, Dr. Spasokukotsky, professor of surgery in the University of Moscow, is trying a procedure based on the researches of Lintvarev of Saratov. Spasokukotsky has not published his results as he does not wish to be swamped with useless requests from patients, but he has given me the following verbal account for this JOURNAL.

Lintvarev has shown that in disease the red blood cells contain a larger percentage of toxins than the blood serum. We have treated three cases of inoperable cancer by re-injecting them with their own blood cells. About 40 ccm. of blood are withdrawn from the patient, the red blood cells are separated and washed and then injected subcutaneously. There is no reaction (rise of temperature, chill or convulsion) whatever although severe symptoms are observed if the blood serum is injected. The first case was an inoperable cancer of the breast. A year ago we gave her ten injections of her own red blood cells and she is still living and even better although untreated she would surely have been dead. She now has free use of her arm and the cancer is smaller. The second patient who had cancer of the oesophagus, a condition usually rapidly progressive and fatal, received three injections, the course of the disease has apparently been arrested as the patient is no worse. The third case (inoperable cancer of the breast) was almost cured by our injections but when we endeavoured to hasten the treatment by using for injection the red blood cells of another cachectic cancer patient she became rapidly worse. This method of treatment the auto-injection of washed erythrocytes has given excellent results in

cases of surgical tuberculosis, especially in tuberculous peritonitis. Rapid improvement has followed in every case in which we have tried it."

A. A. Bogomoletz has retarded the growth of cancer in mice in the following way. The spleen, bone marrow, and omentum (tissues rich in reticulo-endothelial cells) of mice were macerated and made into an emulsion. This was then injected into a number of rabbits, four or five injections at intervals of five days. After a month the blood of the rabbits might be expected to contain antibodies for the reticulo-endothelial cells of the mouse—hemolysins, agglutinins, etc. To see which rabbits had actually developed these antineoplastic bodies they were tested by the Bordet-Gengou method. Small doses of this rabbit serum were found to stimulate, and large doses to depress or "block," the reticulo-endothelial system of the mouse. A batch of over 500 mice was divided into three groups. All the groups were subcutaneously injected with cancer cells from other mice. Group I was used for control, 50 per cent of them developed cancer. Group II was injected with small (therefore stimulatory) doses of the rabbit serum containing the antineoplastic bodies for the reticulo-endothelial cells of the mouse, only 10 per cent developed cancer. Group III was injected with large (therefore depressing) doses of the same rabbit serum, and 70 per cent developed cancer. These data support Bogomoletz's theory that the growth of cancer is dependent upon the health of the reticulo-endothelial system\*.

#### WORK OF CHALATOV

By transplantation of the testicles of young cats to very old ones and ligating the vas deferens at the same time, Chalatoz obtained a growth of new incisor teeth in three cats, 12 to 14 years old. His further studies with cholesterol show that in starvation the blood cholesterol is diminished, but that it rises again just before death. Removal of the thyroids caused a diminution, but extirpation of the kidneys or parathyroids a great increase of blood cholesterol (Nekudov). Resistance of the red blood cells was found (Frankel) to be less in the hepatic than in the peripheral veins, a fact which he considers in favour of the view that haemoclastic function resides in the liver rather than in the spleen, as formerly thought.

#### DIGESTION

##### *Effect of Mineral Waters on the Gastro-intestinal Tract*

The Caucasian mineral waters, taken with food, markedly augment the secretion of gastric juice and shorten the whole period of digestion. The same waters taken half an hour to an hour and a half after food have an inhibitory effect on the secretion of the stomach, due to the water having passed into the duodenum, where it acts when food is taken into the stomach. These waters do not increase the secretion of the bile, but it seems that they hasten its expulsion from the gall bladder into the duodenum (Fursikov, Martinson, et al.). All these waters contain calcium, magnesium, iron, sodium, and free carbon dioxide, some are radio-active.

##### *Effect of Vegetable Juices on Gastric Secretion*

In 1917 it was shown in Pavlov's laboratory by Volborth and others that vegetable juices have a great effect on the secretory action of the stomach. K. M. Bykoff found that vegetable juices taken with meat and other proteins greatly increase the flow of gastric fluid. This was held to afford a scientific basis for the use of the soups made of meat and vegetables which are so popular in Russia. When vegetable juices were taken with carbohydrates the flow was also greatly increased. Bykoff found also that during the first hour fatty foods inhibit the action of the gastric glands, but that if given with vegetable juices the inhibitory phase of the fat completely disappears, and the total quantity of the stomach juice for the whole period is much greater than with fat alone. This experiment explains the use of fatty foods and vegetables together—

for example, butter and cooked apples together give a great flow of stomach juice. From the secretory effect and from the composition of their ferments, vegetable juices must be considered as energetic stimulators. The work was done on dogs with pouches isolated according to the method of Heidenhain and Pavlov.

Later studies showed that tomato juice was the strongest of all known natural stimulants of the gastric secretion, including even meat extracts. During the two and a half hours after giving 250 c.c.m., 163 c.c.m. of gastric secretion was obtained from the little stomach of the dog, 200 c.c.m. of distilled water gave during the same time only 13 c.c.m., and 250 c.c.m. of cabbage juice 8 c.c.m. The juice of cauliflower caused a secretion somewhat larger than that of cabbage, watermelon juice, two or three times greater than distilled water, the juice of cherries and grapes produced the same amount of secretion as distilled water. The simultaneous administration of 250 c.c.m. of tomato juice and 250 c.c.m. of warm mineral water ("nauzui," similar to Apollinaris) called forth a much larger secretion than even the tomato juice alone. When mineral water was added to watermelon juice the secretion was greatly increased. When vegetables and mineral water were given together the combination produced more secretion than either alone.

#### CONCLUSION OF THE SERIES

In concluding this series of articles I desire to reiterate my point of view—that is, I have had no political end to serve, and I have had nothing to prove. My original idea was to present the general medical and scientific facts that I had collected in Russia, in order to give information on an important subject, and at the same time to balance these facts so that the whole series of articles would convey to the careful reader an accurate conception of the situation. The perusal of isolated passages will not, I think, produce a correct impression of the events.

The following conclusions even, I think, be safely drawn. There has been in Russia, from the medical point of view, a truly appalling calamity—intense suffering, indescribable horrors of severe famine, wholesale ravages of disease, extreme general poverty, and bestial conditions of living. Although the effects of this will continue for a long time, the acute stage is passed, and is being followed by one of slow but gradual reconstruction. The disaster was probably due in the main to the accompanying disorder and prolonged deprivations of continued war and revolutions in an already demoralized country. The sweeping political changes came at a time unfavourable for the experiment, and it is therefore more difficult to judge accurately of their effects than of those of the war on disease during this destructive period, but it can be seen that they have already initiated profound general mutations, the full force of which will not be manifested perhaps for a generation—such as, for example, the difference in moral standards and education, the substitution of community and club life for that of the family, and so on.

As the period of destruction has been the most prominent and has had its acute crisis I have devoted more space to it than to that of the subsequent reconstruction, which is only just beginning and is occurring along various lines. Although I have included some recent scientific achievements, these, though given official encouragement, have been mostly in the nature of individual efforts. I intend to treat in more detail later on this stage of reconstruction.

I desire to express my gratitude to Sir Dawson Williams for his consideration in having first helped me with the outline of the material I had collected. To Dr J. W. McNee I am indebted for suggestions about the present article, and to S. G. Kuzanov and I. Guerbatov for assistance in the preparation of material from the Russian.

*Note*—In order to avoid any confusion that might arise from the reference to Pavlov's two books in the footnote to my article published in the *BRITISH MEDICAL JOURNAL* of June 11th 1927 (p. 1070) I desire to say that the volume there mentioned (*Activity of the Cerebral Hemisphere*) is that published by Oxford Press in July 1927, under the title *Conditioned Reflexes*, while the one called *Conditioned Reflexes* in my article is another book, which has not yet appeared in English.

## HARVEY, BACON AND GILBERT

THE *Harveian Oration*, which dates from 1656 and has now been delivered on 208 occasions, has often made the distinguished holders of this high office feel that they are freed with the recitation of an oft told tale, and that the exertions of their predecessors have left them few, if any, new avenues of approach to Harvey's discovery. It is of course true that in founding it Harvey left certain directions, such as a commemoration of all benefactors by name, and an exhortation to the Fellows and Members to 'search and study out the secrets of Nature by way of experiment', but these have been so dutifully followed, especially with regard to the commemoration of benefactors—for example by the late Sir Norman Moore in his Oration (1901)—that recent orators have sometimes been constrained to go rather far afield and to content themselves by references here and there to Harvey's inspiring example and experimental methods. Sir William Hale White in his *Harveian Oration* this year (p. 713) has taken as his thesis one which, at any rate for many years, has not been attempted by his predecessors—namely, the influence exerted on Harvey by his senior contemporaries in this country, Francis Bacon (1561-1626) Lord Chancellor and philosopher, and William Gilbert (1540-1603) President of the Royal College of Physicians (1600), and the Father or experimental philosophy in this country, whose *De Magnete Magneticisque Corporibus et de magno Magnetic Tellure Physiologia nova* (1600), declaring the earth to be a magnet was the first great scientific book published in England.

As Harvey was in Padua from 1600 to 1603 it has naturally been assumed that he was stimulated there by the Italian atmosphere to research on experimental lines. In a lecture at the Royal Institution on Harvey on January 25th, 1878 the year in which the tercentenary of Harvey's birth was celebrated in London the late Professor F. H. Huxley considered the question whether or not Bacon had influenced Harvey's mind and method of investigation and very definitely decided against this possibility on the grounds that there is not any trace in Harvey's works of Bacon's writings and that Bacon's *Novum Organum* (1620) was not published until some years after Harvey had given his demonstration of the circulation of the blood in his *Lumleian Lecture* on April 17th 1616 at the Royal College of Physicians, the setting of which Sir William Osler so graphically painted in his *Harveian Oration* twenty years ago. With a wealth of argument and quotation Sir William Hale White contends that there is much circumstantial evidence though admittedly not any direct proof of Bacon's influence on Harvey. In so doing he brings out his sincere admiration for both the man and the manner of Bacon's writings and incidentally throws some interesting light on Bacon's personality, his introspection and sufferings from the goit and the stone, thus recalling Swedenborg's afflictions and Erasmus's epigram: 'I have renal colic, you have gout, we have married sisters.'

Stress is skillfully laid on the probability that Harvey

had read and was influenced by Bacon's *Advancement of Learning*, which came out in 1605, before Harvey had started on his experimental investigation of the circulation and that it mentored the experimental method which Harvey later practised with such efficiency and excellent results. Sir William Hale White meets the objection raised by Huxley and reiterated in a leading article in our columns a year ago (1926 p. 311), that as the *Novum Organum* was published in 1620 Harvey could not have been influenced and stimulated by it in his methods of investigation. He points out that while engaged in his writings Bacon freely discussed their substance, certainly with his chaplain and probably with his medical attendants, of whom Harvey was one though it is not claimed that Bacon utilized Harvey's professional services before the delivery of the *Lumleian Lectures* of April 1616, when Harvey first demonstrated his discovery, it is argued that it does not follow that the contents were unknown until the masterpiece was printed. Later on, however, the orator explained the absence of any reference by Bacon to Harvey's discovery by the death of the fallen Lord Chancellor in 1626 before the publication of the *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* in 1628 so by parity of reasoning it might be suggested that Harvey, his physician had verbally told him some details of a matter of such absorbing scientific interest. From consideration of Harvey's writings Sir William Hale White infers that, except for the grandeur of Bacon's language Harvey's opinions might well have been expressed by Bacon and that the minds of these two outstanding men of their time ran on similar lines so that they thought alike. The evidence adduced from the famous quotation by John Aubrey who as a gossip has been described as 'a kind of immature Boswell', to show that Harvey was not influenced by Bacon is criticized with much ingenuity and effect.

Turning to the question of the influence exerted by William Gilbert on Harvey, the orator makes it abundantly clear that as a friend of Dr Lancelot Browne, whose daughter Elizabeth became Harvey's wife in November, 1604 Gilbert must have been well known to Harvey by repute, though perhaps not in person (for he died in 1603), as a leader in medicine as well as in science and the author of his great work which burst upon the world just when Harvey was in a particularly receptive state of mind and full of energy for his future life of epoch-making research. This interesting and closely documented Oration, a labour of love and dictated by respect for the father of modern physiology, closes with a brief sketch of the scientific atmosphere in the early years of the seventeenth century which leads up to the conclusion that Harvey must have been familiar with the teaching of Gilbert and Bacon.

## THE SEROTHERAPY OF POLIOMYELITIS

PROFESSOR G. ETIENNE of Nancy has devoted much attention during recent years to the subject of poliomyelitis and its treatment by serotherapy. The use of convalescent serum was suggested so long ago as 1910 by A. Netter and subsequent investigations have shown that this procedure is efficacious in certain cases. Professor Etienne has now published in the issue of the *Revue Médicale de la Suisse Romande* for August 25th, a careful summary of what is known about myelitis and its treatment. He prefers the term 'myelitis' to the more classical one of 'poliomyelitis' because

in the adult, with whom he has been mainly concerned, the infective process is more diffuse than in the infant, in whom myelitis is limited more definitely to the anterior cornua. In his present contribution he draws attention to the striking analogy between the clinical evolution of anterior poliomyelitis and that of paralytic rabies. Research along the lines of Pasteur's classic study of rabies has established experimentally the specific action of the virus of anterior poliomyelitis on the nerve centres, the filterability of the virus, its biological characters, its extension along the nerve trunks, the possibility of its transmission to monkeys and of immunizing them by successive doses of virus, and the neutralizing power conferred on the blood of these animals. Monkeys may be inoculated by intraperitoneal, intradural, subcutaneous, intravenous, or intraintestinal injection, also by the nasal route. It appears that the virus is eliminated by the pharyngeal mucosa and the tonsils. This is an important point, in view of the fact that myelitis may follow cancrina or sore throat, and that "carriers" may constitute a danger in epidemics. Although the infective agent has not been definitely isolated, it has been shown that the blood of apes which have survived an attack of paralysis can neutralize the virus, and that the serum of convalescent patients has the same power, provided that the injections of serum have been commenced within eighteen or twenty-four hours of infection.

Professor Etienne describes the application of serotherapy in three periods of the infection: in the initial pre-paralytic phase, in the stage of extensive paralysis, and in that in which the palsies have become established. Several observers have found that the majority of patients who are treated with the serum of convalescents during the first phase do not develop paralysis to any great extent. When injections are given during the second stage striking results have been reported. In most cases there is definite arrest of the paralytic process, and very often recovery, sometimes rapid, from an existing paralysis. In regard to the third phase, as a rule a good deal of the paralysis clears up, leaving a residuum that is usually permanent; it is thought that in cases treated with serum recovery is more rapid and more complete, but it is obviously necessary to intervene before definite destruction of medullary cells has occurred. As in all forms of serotherapy treatment must be undertaken at the earliest possible moment. Since the quantity of serum available for injection is necessarily very small, it is advisable to inject it by the intrathecal route, which also favours acceleration of the response. The quantity injected ranges between 3 c.c. and 13 c.c., with larger doses meningeal symptoms, such as opisthotonos, frequently occur. Netter recommends the repetition of injections (generally about eight times), but this appears to intensify the meningeal reactions.

On account of the difficulty in obtaining sufficient quantities of the serum of convalescents, many attempts to immunize animals have been made, chiefly at the Pasteur Institute in Paris. Etienne records nine cases of complete recovery after repeated intrathecal injections of serum prepared at the Institute. In one case (a man aged 40) treatment was only commenced seven weeks after the onset of the disease, when he was completely paraplegic with considerable muscular atrophy, an important clinical point is that the fever persisted. In ten days 120 c.c. of serum was injected, and within eight days the patient had improved, the reflexes returned, and he began to walk, three weeks later he had

recovered completely, except for slight extensor paresis and talipes equinus. One failure is recorded in a man aged 62 who had severe diabetes: he died of heart failure, in spite of definite improvement in the paraplegia. Professor Etienne adds that this serum is not effective in other apparently similar diseases, such as epidemic encephalitis and disseminated sclerosis. Netter's method of employing the serum of convalescents has given generally satisfactory and sometimes remarkable results, and the conclusion is that it has definitely passed out of the experimental stage.

## HOSPITAL POLICY AND LEGISLATION

At the Autumn Dinner of the British Medical Association Mr. Neville Chamberlain, the Minister of Health, made a speech, fully reported in the *STANDARD* for this week, which greatly impressed his audience. He outlined the legislation which he hoped would be passed at early dates for assisting the work of his department in furthering national health. Not the least part of the interest excited by his speech was due to his sketch of ideas on hospital policy. These ideas he has since set out in an interview which appeared in most of the daily papers on October 15th. From these sources it appears that the Minister desires to secure three main things in any reform of the Poor Law so far as this will affect hospitals. First, that there shall be association of hospital activities and not competition. This association, he claims, is necessary if the voluntary hospitals and their invaluable associations and the spirit that informs them are not to be lost through pressure by the statutory hospitals, whose resources may be termed (in comparison with the voluntary hospitals) as unlimited.

Such an association would, he suggested, be best brought about by the formation of a joint body embracing both the municipal and voluntary hospitals, which should decide upon the line of development of hospitals where they were needed, their types and so forth, and also secure interchanges between the hospitals both as regards patients and staff. Change of control of the Poor Law infirmaries from the smaller statutory boards of guardians to the municipalities he considers necessary, if only to secure the removal of the old stigma of pauperism from these great institutions. It would facilitate also arrangements for the interchange of patients. Such a scheme should make it easier for patients to secure admission to hospital, and for the home doctor to keep in touch with his patient when in hospital. The general practitioner should be represented upon the joint body of control and be in closer touch with institutional treatment.

Further, he envisaged the extension of hospital treatment so that not only the poor who cannot pay will be treated, but those who are able to pay more or less completely for the treatment they need and those who would be able to pay a full fee both to the hospital and their own specialist whose treatment they desire. "Nobody should be deprived of institutional treatment." Our present system, he holds, is illogical and wasteful, the custom of making differentiation in the treatment of a sick person according to whether he could or could not pay he deems absurd. His proposal to make the Poor Law hospitals into municipal hospitals he maintains, did not mean of municipal socialism for it was not a transference of a private hospital to public ownership. Some have admitted, however, that it meant doing away with the voluntary system, but that was the very opposite of what he wanted to do. His desire was to save the

voluntary hospitals from a danger now over-hadowing them.

The British Medical Association has formulated its hospital policy after prolonged deliberation through Council, committees, Divisions, and Representative Body. Now we have a Minister of Health who has shown himself particularly interested in the progress of medicine and bold enough to lay the outhnes of his hospital policy before the public. When we compare these two drafts of policy, the Association's and his, we are grateful to find that there is so large a measure of agreement. There is a happy significance in this fact, a happy augury for the successful accomplishment of a real reform of our hospital system in the near future which shall be both effective and British.

#### THE HARVEIAN FESTIVAL IN LONDON

THE HARVEIAN Festival was celebrated in London in the usual way by the Royal College of Physicians on St. Luke's Day (October 18th). The Harveian Oration, delivered by Sir William Hale-White, is printed in full in the opening pages of this issue and elsewhere we make further editorial reference to it. It was delivered in the afternoon, when the Baly Medal was presented to Professor A. V. Hill, F.R.S. At midday the President (Sir John Rose Bradford) and the officers and some members of the Council of the College attended Bow Church, Cheapside, to hear the annual sermon preached under the Sadler Trust. The preacher was the rector of the church, the Rev. Gordon Ponsonby, and the sermon was principally a recital of the names and achievements of distinguished Fellows of the Royal College who had passed away during the year. Among others whom Mr. Ponsonby recalled to the mind of his hearers were Francis Warner, who laboured on behalf of feeble-minded children, Llewellyn Phillips, a name which Gonville and Caius men remembered with special pride, who spent twenty-five years of his life training medical students in Egypt, Thomas Clavre Shaw, who took his first degree in London as long ago as 1860, and was a pioneer in advocating the establishment of mental clinics connected with general hospitals, Sir Isambard Owen, who after twenty years as a physician in London seemed to have found a more congenial sphere of labour in educational administration where his sympathies had full play, Thomas Robert Bridshaw, a loyal and lovable colleague, who laboured among the hard-headed folk of Lancashire, Ernest Henry Stirling, a man of exceptional distinction, who greatly advanced the knowledge of physiology, Sir Brian Donkin, who made notable contributions to the study of the inheritance of mental characters, Charles Wilberforce Daniels, who, after working in tropical colonies, had served as director of the School of Tropical Medicine and Adrian Stoke, perhaps the most pathetic of all these losses, who was cut off at the age of 40, though not too soon for him to have exemplified how abundantly he possessed the great virtues of the medical profession—patience, courage, selflessness, and humanity. The preacher also spoke of one, not a Fellow of the College, of whose death he had learned only within the last few days—Sir William Macpherson, a lifelong friend of his own, with whom he went to school more than half a century ago. The preacher's own chief recollection of him was of his great tenacity of purpose in all that he undertook. In addition to this he was a humble man at heart, reverent in his thoughts, quiet in his manner, and unswerving in his work, he approached death at the last with the same calm courage he had looked it in the face more than once before in other lands. He and his like, said the preacher, still spoke to those who followed in their step. He was a wise man who said that the dead ruled the world. Their bodies had been laid in the grave, but

their voice was still heard. In the evening a dinner was held within the College. Among the guests were the Dean of Westminster, the Speaker of the House of Commons, the Secretary of State for War, the President of the Royal College of Surgeons, the President of the Royal Academy, and the Ministers of the Grocers and the Merchant Taylors Companies. The Speaker and the Secretary for War responded to the toast of "The Guests," and the latter made a very sympathetic reference to the Air Force Medical Service.

#### TREATMENT OF EARLY MENTAL DISORDERS

EXPERIENCE has shown that there is no more urgent problem in the case of patients afflicted with mental disease than the adequate treatment of its early stages. In this we have to some extent lagged behind other countries—especially perhaps Germany and the United States of America—owing partly to the legal difficulties under which we still labour in bringing patients with slight and early mental disorders under control, and partly to the constitution both of our large public mental hospitals and of the smaller registered houses, which are bound either by law or by economic reasons to accept all patients, both early and chronic who are sent to them. In the larger public institutions a segregation of patients in the early stages of mental disease is sometimes possible and is often attempted but it is rarely practicable in the smaller mental hospitals and houses. In another column we publish a description of the Reception Block which was opened last week at St. Andrew's Hospital, Northampton. Into it all persons suffering from recent or acute psychoses who are sent to the hospital will be admitted and treated apart from the more chronic cases, until they recover sufficiently to be discharged or pass into a subacute or chronic stage. Here the ideal of the complete separation of patients with recent and often curable conditions from cases of hopeless or long-standing insanity will be possible, since the Reception Block has its own entrance, stands in its own grounds, and is under the care of a separate staff. An equally important feature is the provision of laboratories for the complete investigation of every case admitted to this block. In this matter we have been much behind the facilities enjoyed by psychiatric clinics and mental hospitals of some other countries, in our smaller licensed houses, particularly the clinics-pathological examination of patients has always been difficult, yet attention is being more and more strongly directed to the etiological importance of physical disease in the pathogenesis of insanity, and especially to disturbance in metabolism and to intoxication from foci of sepsis or other infections. If these factors are as important as some believe, it is obvious that they should be dealt with in the earliest possible stage of the illness. The influence of environment and of various forms of physiotherapy in the early stages of mental disorders has long been recognized in other countries, but in England, though theoretically taken into consideration, there has been no adequate opportunity of making a complete study of its influence on the rate of cure. In the United States valuable work is being done in this connexion, but the St. Andrew's Hospital, Northampton, is, we believe, the first institution in England which has been able to devote a whole block and whole-time medical men to the study of these influences. The difficulties of cure and treatment in mental disease must be very greatly increased when the patients are of necessity, in the constant company of hopeless and chronic cases. In all other diseases efforts are made to keep the acute and curable cases away from the hopelessly incurable or recumbent of the mental effort produced. It stands to reason that those patients in mental hospitals who present signs of lessened mental confusion must be depressed in their saner moments by close contact

with the wrecks of human civilization. The congratulations of the medical profession are due to the committee and medical staff of St. Andrew's Hospital for this welcome innovation in the treatment and investigation of mental illness. The Board of Control and all those in authority in asylums have been much preoccupied with the low recovery rate in mental disease as compared with other forms of disease, but, as the chairman of the Board of Control said at the opening ceremony, more favourable results may be looked for as a result of the experience gained at Northampton. The Lord Chancellor also laid stress on the desirability of all mental institutions in this country taking steps, so far as in them lies, to establish similar hospitals.

#### THE TRAFFIC IN DANGEROUS DRUGS

SEVERAL recent events have directed attention afresh to the traffic in opium and other dangerous drugs and the means which have been invoked with a view to effect both national and international control of that traffic. At the twenty-fourth Interparliamentary Conference, held recently in Paris (August 25th to 30th), a series of resolutions was carried declaring "unanimously" that the abuse of the drugs in question will only be reached by "limitation of the culture of the poppy and coca leaves and of all narcotics to the recognized amount needed for medical and scientific purposes, this measure to include the total suppression of the use of opium for smoking." It is true that later resolutions exhibited signs of compromise between those groups which approved the agreements arrived at by the Geneva Conferences of 1924-25 and those which did not. Thus a period of fifteen years was indicated within which the suppression of opium smoking contemplated by the Hague Convention of 1912 should take effect, and while some groups urged the ratification of the Geneva agreements, others pressed for their revision in accordance with the principle contained in the above-quoted first resolution, which had been passed unanimously. On September 16th the Assembly of the League of Nations received a report from its Fifth Committee dealing with the opium traffic. This report emphasized the insistence of the Advisory Committee on Dangerous Drugs on the necessity for a general and apprehension of what the illicit traffic in dangerous drugs means "in terms of human suffering, misery, and degradation," as well as on the committee's serious statement that the action taken by several Governments "falls far short of their contractual obligations" under the Hague Convention of 1912. Attention was called to the fact that Turkey had not yet ratified the last-named treaty, nor vouchsafed a reply to the secretariat's communications on the subject. The Fifth Committee further complained that several Governments had failed to comply with their stipulated undertakings to furnish information in regard to the commerce in noxious drugs of their respective countries. The change in constitution of the Council of the League of Nations has caused a setback in the matter of putting in force the Geneva agreements of 1925. It will be remembered that the effectuation of the Geneva Convention was dependent upon its ratification by ten signatory States, including seven of the principal States represented on the Council, two of which must have permanent seats thereon. By the disappearance of Belgium, Czechoslovakia, and San Salvador from the Council three of the requisite ratifications have been lost, only those of Great Britain, France, and Poland remaining effective. Early this month a special session of the Advisory Committee on Opium, etc., was held at Geneva. Further evidence of the "enormous scale" of the illicit traffic in dangerous drugs was forthcoming, and of its backing by "huge financial resources." Proposals were put forward for placing the manufacture of all dangerous drugs in Governmental hands or for an "international union of alkaloid manufacturers," which how-

ever, were referred to a subcommittee. The committee lamented that only three States, members of the League Council, out of the seven required had ratified the Geneva Convention, and made an "urgent request that the matter shall receive serious consideration at the next meeting of the Council."

#### A PROPOSED ASTHMA RESEARCH COUNCIL

WE have received a notice informing us that an Asthma Research Council has been formed with the Earl of Limerick as president, Lord Glenavy as vice-president, and Captain F. L. M. Boothby, C.B.E., as honorary secretary. The writers state that according to the Registrar-General's returns more than 2,000 men, women, and children die from asthma and its kindred diseases every year, and they infer that for every sufferer who dies there are many thousands whose lives are made a burden to them by the paroxysms of this malady. They go on to assert that, though palliatives have been found, no certain cure exists, and, further, that the cause of asthma is unknown. The council, they state, has been established to serve as a central body organizing research and carrying it out systematically. Its office is at 12, Bedford Street, W.C.2. Asthma is so distressing and incapacitating a disorder that we can well understand sufferers from it desiring to institute inquiries in the hope of finding some cure, or at least some mitigation, but the investigation of the cause of asthma is a very complicated problem, it is not so much a disease in itself as a symptom of some defect, functional or structural, which may not be, and probably is not, of the same nature in all cases. For this reason we think that the first step the proposed council should take would be to obtain from medical sources the most recent information available as to what has already been done, and of the medical work which is now in progress. For any effective inquiry a team of workers would be necessary, such as can only be found at a general hospital. Were the council able to finance a special asthma out-patient department such as exists in several American cities, and succeed in having it attached to some general hospital, a group of cases could be thoroughly investigated from every point of view. A physician, laryngologist, and radiologist already on the staff and interested in asthma might be put in charge, and some younger man, also if possible interested in the disorder from a pathological point of view, might be appointed to devote his whole time to the work as a research fellow. Such a research fellow would begin by spending some time at Leyden with Professor Storm van Leeuwen, at Mont Doie, at Bad Reichshall, and at the asthma clinics in Boston, New York, Philadelphia, and at the Mayo institution at Rochester. When he got to work in this country he would need skilled secretarial assistance for the collection and analysis of statistics. Those quoted by the promoters from the Registrar-General's returns are probably fallacious. The 2,000 deaths mentioned must include bronchitis complicated by asthma, and probably also conditions known as cardiac and renal asthma, neither of which has anything to do with real asthma. We should rather doubt whether half a dozen people die on an average in any year from uncomplicated or nervous asthma in England and Wales. A vast mass of statistics can, no doubt, be collected, but unless very carefully digested and examined from all points of view they are not likely to lead to any helpful results.

#### MALARIA AND NATIONAL DECAY

CURTAIN letters on malaria and national decay appeared in the *Times*, the writers of which seemed to be unaware that as regards Greece, with which they concerned themselves, it had received almost exhaustive treatment a score of years ago. Mr. W. H. S. Jones of Cambridge published,

in 1907, a small book on *Malaria: A Neglected Factor in the History of Greece and Rome*, and two years later followed up the subject in *Malaria and Greek History*. Both these books were noticed in our pages (BRITISH MEDICAL JOURNAL 1909, vol. ii p. 1349). The first work was reissued in 1920 with some additional evidence and an introduction by Sir Ronald Ross but the great mass of historical facts and references collected by Mr. Jones is to be found in the second book.<sup>1</sup> It is generally accepted that the national character of the Greeks changed for the worse between the fifth and third centuries before Christ, but there is not the same consensus of opinion as to the cause of this change. Mr. Jones and some others attribute it to the prevalence of malaria as a new endemic disease. One of the difficulties in discussing this question is the lack of precise diagnosis and the consequent doubt as to the nature of diseases known by such names as *επιπνοια* *καυσος* *η-ιαλος* *θερμη* etc. but notwithstanding this, it seems certain that by the third century B.C. the greater part of Greece and of the south of Italy was at least so malarious as it is to-day, but in order to show that this was the cause of national decay it is necessary to produce evidence that in the great days of the sixth century malaria was unknown or rare. The evidence which Mr. Jones relied on is hardly convincing on this point and indeed, there is a strong pre-emption in favour of the contrary view. In a paper with which he opened the discussion on the structure and function of the spleen during the Annual Meeting at Edinburgh Professor John Tait quoted from Hippocrates (BRITISH MEDICAL JOURNAL, August 20th, 1927 p. 291) evidence of the universal prevalence of malaria in his day. Apparently a large spleen was considered as normal for Hippocrates says "When the body flourishes the spleen wastes." Mr. Jones and Dr. Withington, on the other hand, consider that malaria was rare in the time of Hippocrates, and that the degradation of medicine from the rational school of Hippocrates to the miracle-working charms and snakes of the Esculapion temples was due not only to mental enfeeblement from malaria but also to the failure of the rational physicians in the absence of quinine to cure the disease. According to this ingenious theory the sufferers in despair turned to magic and dreams and incantations for the help which science could not give. But whatever influence malaria may have had it must not be forgotten that there were other potent causes of decay in the Hellenic peninsula acting at the same time. The want of union between the city-states and the frequent and devastating wars between them—notably the Peloponnesian war and the war of Athens with Syracuse—exhausted the people and left the survivors of war and pestilence enfeebled in mind and body. Yet in Attica Sparta Corinth and their neighbours were exhausted the Greek race was by no means done with, for its colonies long survived and flourished in Asia Minor, Egypt, and the Mediterranean, and when Rome had made a physical conquest of Greece the vanquished avenged themselves by a spiritual conquest of the victors. After all, the later so-called Roman Empire was largely Greek and Byzantium which for centuries was the centre of western civilization and learning was a Hellenic city, just as much as Alexandria. A writer in a recent number of *Nature* refers to the theory of Mr. W. H. S. Jones as being now generally rejected, but, nevertheless we think with our reviewer of 1909 that he and Dr. Withington have added a fascinating chapter to medical history and made a suggestive contribution to the study of the causes which influence the destiny of nations.

<sup>1</sup> *Malaria and Greek History*. By W. H. S. Jones, M.A., Fellow of St. Catherine's College, Cambridge, Assistant Lecturer at the Perse School. To which is added *The History of Greek Therapeutics and the Malaria Theory*. By E. Withington, M.A., M.B., Balliol College, Oxford. Macmillan & Co. Ltd. The University Press, 1909.

## ALL ABOUT TOBACCO

THE Norman Kerr Memorial Lecture of the Society for the Study of Inebriety, though usually devoted to the consideration of alcoholic problems, really has wider applications and in 1925 Sir William Willeox took the opportunity of authoritatively discussing drug addiction. Dr. W. E. Dixon has followed this excellent example, and his exhaustive and extremely interesting review of the tobacco habit, which is published in this issue (p. 719), is most appropriate in many respects especially, perhaps, in connection with the question of the effect of smoking on intellectual activity and the opinion, expressed by Dr. J. R. Larp and based on observations made on the students of Antioch College, Yellow Springs, Ohio, that the non-smokers come out better than the habitual smokers. On this vital point Dr. Dixon considers that the interpretation of the results given by the experimental tests applied, which admittedly point to some inferiority on the part of the smokers, is so complicated by various factors as to be negligible. He comes to the comforting conclusion that on the whole smoking in moderation does not exert any harmful effect on the normal central nervous system. But the important question whether or not strict moderation in smoking leads to a cellular degeneration as a rule or only exceptionally is left open for further investigation. It may be that the constitutional make-up is a determining factor in this respect, for Buijger's thrombo-angiitis obliterans though not absolutely confined to male Hebrew smokers, occurs among this ancient race in such an overwhelming majority of the cases that Dr. Paulus Weber's alternative title of "non-splinitis arteritis obliterans of Hebrews" has met with approval. It is rather attractive to speculate why smoking appeals to man and to the modern young woman. No doubt it exerts a mild stimulating effect followed by a soothing influence, so that it is adopted freely by both the dull and the irritable, but in addition the influence of rhythm, which forms part of the ritual of preparing and smoking a pipe, may—as in dancing, singing, and chewing gum—provide some satisfaction. The broad survey of the aspects of tobacco smoking given in this Norman Kerr Memorial Lecture contains a number of pharmacological points on which the lecturer has made observations in his laboratory, and thus there is an interest additional to the historical summary and the critical review of the literature. The relative importance and proportions of the constituents in various tobaccos and the smoke they yield have been investigated, and it was found that the pyridine contained in the smoke of smouldering vegetable material, including tobacco and coltsfoot leaves (the latter of which was at one time sold as a harmless smoking material for boys) has an irritating effect, and may produce diarrhoea, vomiting, and the early signs of shock. It will perhaps be disappointing to the smokers who feel attracted to denicotinized cigars to hear that Storm van Leeuwen found that their smoke contains as much nicotine as that from the same brand of cigars not submitted to the process of denicotinization, the explanation of this at first sight puzzling result would appear to be that the amount of nicotine in tobacco is no criterion of that in its smoke.

## THE HEALTH SERVICES OF NORWAY

THE Central Health Department in Norway is under the charge of a chief medical officer nominated by royal decree. It consists of two sections—a health section under a medical officer, and a pharmaceutical section under a pharmacist. Attached to the Central Department are the leprosy service, the antituberculosis service, and the service for the insane together with a vaccine institute for the preparation of serums and vaccines. The local authorities

for health are, in rural communes, the communal council, and in urban communes a separate health committee. The chairman of the council or health committee is the district medical officer, who is appointed by royal decree, and whose duty it is to supervise the medical practitioners, chemists, dentists, midwives, and assistant vaccinators of his area. The communes of the whole country are grouped into twenty prefectures, each of which has a medical officer-in-chief who supervises the district officers. The working of the system has recently been reviewed for the Health Organization of the League of Nations by Dr H. M. Gram, director of health services, Oslo. The infectious diseases required to be notified by medical men in Norway are of the same type as in England. One difference is that open tuberculosis only is notifiable, another is that venereal disease is included. Leprosy is not notifiable by medical practitioners, but chairmen of health committees keep a list of local lepers and report on them annually to the Central Department. For the bacteriological diagnosis of infectious disease there are laboratories at Oslo and Bergen, and municipal laboratories in some of the chief towns, but Norway is a land of such wide spaces that it is difficult for country doctors to avail themselves of these facilities. In any case it is not intended that notification should await bacteriological confirmation. The Central Health Department has issued a manual for the guidance of practitioners on these points. All towns and most of the rural areas furnish monthly reports on epidemic disease to the central authority. Their annual reports, which are more correct, are tabulated in an official year-book, which is published in French and Norwegian. The only midwives allowed to practise are those who have gained a diploma in a Norwegian public school or in a school recognized by royal decree. Nurses and masseurs of either sex are under the district medical officers. Vaccination against small-pox is not compulsory, but no person can be confirmed or married in the National Lutheran Church or admitted to a high school without a certificate of vaccination. There is an anti-vaccination propaganda of some activity, but vaccination is gradually becoming more general, and is stimulated by every outbreak of small-pox. There are no public services for the treatment of venereal disease, which work with some friction between rural and urban communes. Rural patients migrate into the towns in order to obtain better treatment, and the rural communes feel and voice their grievance at being required to meet the charges. A bill providing for State control of this service is at present under consideration. There is local abundance of water supply in Norway, but surface water is scarce and wells are often defective. Some towns use river water purified by filtration and chlorination. The few water-borne typhoid outbreaks of the last thirty years were traced to isolated wells. There is a temperance movement in Norway. During the late war prohibition was introduced of all drinks containing more than 12 per cent of alcohol. The result was that smuggling and illicit distillation increased enormously. It is now a penal offence for a soldier, a driver or conductor of a tramway car, a railway servant, or a driver of a motor vehicle to consume a beverage containing more than 2.5 per cent of alcohol while on duty or within six hours beforehand.

The Thomas Vicary Lecture before the Royal College of Surgeons of England will be given by Dr George Parker on Thursday, November 3rd, the subject of the lecture will be "The early development of hospitals." The Bradshaw Lecture before the same College will be delivered by Sir Cuthbert Wallace on Thursday, November 10th, it is entitled "Enlarged prostate a review." Both lectures will be given in the College at 5 p.m.

## Nova et Vetera.

### THE SERJEANT-SURGEONS AND THE SERVIENTES REGIS CONTRASTED

SOME account of the Serjeant-Surgeons to the King was printed in "Nova et Vetera," British Medical Journal, 1925, vol. 1 (p. 224), but it may be worth while to compare the serjeant-surgery with other royal serjeantries. Domesday Book calls the King's Serjeants *servientes regis*. Serjeantry in older times indicated a tenure of land, and as such was capable of descent from father to son. This leads me to the point of this note, which is that the serjeant-surgery can never have had anything to do with a professional land tenure. One can understand, to take an extreme and unauthorized example, a feudal noble owning a manor by the tenure of serjeantry of cutting the King's corns before the coronation ceremony. Anyone can make shift to cut a corn, but the son of a surgeon, even if he follows his father's profession, need not of necessity be of any use in it, and it is inconceivable that a serjeant-surgeon could have held land by serjeantry tenure of a professional sort. The whole idea was that of personal service. Father, son, or grandson could officiate with the napkins at the coronation banquet, but not necessarily with the surgery of the period, rude though it may have been.

There was, however, nothing to prevent a doctor holding land by serjeantry when the tenure implied service of a different kind from the practice of his profession. Round instances the holding by Walter Devenish of land in Devon by the serjeantry of finding three arrows when the king should hunt on Dartmoor. The land in question was Shiradon in Dean Prior, on the south-east border of Dartmoor. Roger de Mirebell had forfeited it for homicide, and Henry III had transferred it to Walter with the same service. Now Walter to Dorencis was Hubert de Burgh's physician. Round observes that this is a typical instance of petty serjeantry, which John defined in the Great Charter (1215) as the service of supplying us with knives, arrows, and the like. The classification of free tenures was as follows: frankalmoin, military service, serjeantry, and free socage. Littleton, in Tenures, sec. 153, wrote as follows:

"Tenure by Grand Serjeantry is where a man holds his lands or tenements of our Sovereign Lord the King by such service as he ought to do in his proper person to the King, as to carry the banner of the King or his lance, or to lead his army, or to be his marshal, or to carry his sword before him at his Coronation, or to be his sewer at his Coronation or his earlier, or his bath, or to be one of his chamberlains of the receipt of his exchequer, or to do other like services etc. And the cause why this service or to do other like services etc. And the cause why this service is called Grand Serjeantry is, for that it is a greater and more worthy service than the service in the tenure of escheage (knight service). For he which holdeth by escheage is not limited by his tenure to do any more especial service than any other which holdeth by escheage ought to do (the service due from a knight's fee was uniform), but he which holdeth by Grand Serjeantry ought to do some special service to the King, which he that holds by escheage ought not to do."

All serjeantry ranked below knight-service and above socage. Tenure by serjeantry is as old at least as Domesday Book. Round gives the following instances occurring in the Book: Round—Surrey, Odard, balistarius of Moulsey, Tezeln, surveyor—Surrey, Odard, balistarius of Moulsey, Tezeln, surveyor the cook, kitchen-service Hants William, arcuarus (archer) of Bentley, Geoffry of East Worltham (marshal ser), Miles, porter at Winchester Castle Dorset Omund, baker-service Somerset John, usher-service Devon William, porter at Exeter Castle Cambridgeshire Erchenger, baker-service Essex Walter the const Suffolk Ralf, balistarius of Burgh, cross-bowman service. We may therefore define serjeant-surgery as the personal professional service to the King without the holding of land by serjeantry of that particular service.

If any readers are inclined to think that my inference of cutting corns is improbable to a high degree, let them

remember that the "mighty Norman houses of Bigod and Giffard held, in succession, an Essex manor by the service of scalding the King's swine."

I am afraid that those who look for facts about the Serjeant-Surgeons in this article will find more of serjeantry than of surgery, but I hope it will be conceded that I am correct in my assumption. I assume, though I do not know, that a similar train of reasoning would apply to the serjeants-at-law.

In conclusion, I must state that I am indebted to J. Horace Round's *The King's Serjeants and Officers of State* (1911) for the facts relating to serjeantry which are recorded here.

R. R. JAMES

## A MENTAL RECEPTION HOSPITAL

### OPENING CEREMONY AT NORTHAMPTON

THE new Reception Hospital of the St. Andrew's Hospital for Mental Diseases, Northampton, was formally opened, in the presence of a large company, by the Lord Chancellor, Viscount Cave, on the afternoon of Friday, October 14th. The chair was taken by the Marquess of Exeter, president of the hospital. Lord Cave, in his address, pointed out that this was the first hospital of the kind to be established in England for the treatment of recent cases of mental illness entirely apart from chronic cases and he hoped that other institutions would follow on these lines. He also stated that he knew of a fact that the report of the Royal Commission on Lunacy was under the active consideration of the Government.

The conception of the governors of St. Andrew's Hospital that all mental patients—whether voluntary boarders or certified—who are recoverable, and who are likely to respond to treatment, should be received in a separate hospital, far removed from patients suffering from chronic forms of mental disorder, was first taken into active consideration in 1914, but the war prevented its realization until 1924, when the foundation stone of the building was laid. The cost of its erection and equipment has been £68,000.

### *The New Building*

The new reception hospital is built on the bungalow plan, with a central two-storied block. It faces south and has its own separate entrance gardens, and recreation grounds. Accommodation is provided for sixteen patients of each sex and also for the sister-in-charge and even nurses. On both the male and female sides are large dormitories opening on to wide verandahs on to which the beds can easily be wheeled. There are a number of separate private bedrooms and private sitting rooms are provided for patients who require them. All the patients' rooms face south, looking out over a wide agricultural valley, and the solarium on which the general sitting rooms open get the sun all day. The dining rooms for the patients are close to the central kitchens, and are arranged with tables, each seating four persons.

Each side has a large room specially set apart for clinical work. Here a complete survey of the physical and mental state of the patient is made. In addition to adequate provision for ear, nose, throat and eye examinations, and preliminary survey of the teeth, ample facilities are provided for the special examinations that modern bacteriological and biochemical methods demand. The preliminary blood examinations and fractional test meals are also carried out here. The investigation of hidden focal sepsis will be a special feature, and a system of case recording has been devised which will facilitate the periodical overhaul of each patient and the accumulation of facts relating to the effects of varying forms of treatment. Great stress is laid on the importance of this overhaul, and it is undertaken at intervals of not more than two months.

The laboratories, on the first floor of the central block, are an important part of the scheme. Two are provided one for bacterial investigation and morbid anatomy, the other for biochemical investigations. Here the detailed examinations of the blood, urine, stomach contents, faeces, cerebro-spinal

fluid, and excretions of each patient are carried out. The bacteriological laboratory, in addition to being completely fitted out with everything necessary for such work, is provided with special apparatus for continuing and elaborating the researches of the late Dr. W. Ford Robert on (bacteriologist to the Scottish asylums) on anaerobic bacteria and their relation to neuro-toxaemia, which promise to throw important light on mental disease. The biochemical laboratory is also fully equipped for its purpose, and efficient sterilization and preparation rooms are adjacent. It is intended to carry out extensive researches in all branches of mental disease in order to determine how far infective processes are active in the causation and what help can be obtained in the fight against them. The clinical and laboratory staff will be in constant consultation on all subjects relating to treatment.

On the first floor of the central block is a fully equipped operating theatre with anaesthetic and sterilizing rooms adjoining, and a bed-carrying lift is provided so that patients can be wheeled from their rooms to the theatre. On the ground floor of this block there are consulting rooms for psychotherapy, a medical library and dispensary, in addition to the dental room, and x-ray and electrical departments. The dental room has an x-ray outfit so that photographs can be taken without the patient moving from the dental chair. The x-ray department is provided with a very complete screening outfit, and the couch embodies all the latest ideas and improvements. It is fitted with a Potter-Buckey diaphragm. The set will provide a peak voltage of 170,000 and every form of treatment, except deep therapy, can be carried out here. The control of the current is so placed that there is no possibility of a patient getting access to it. The electrical department is fully equipped with the most modern apparatus, and the rooms have been furnished with the object of making the patient as comfortable as possible while undergoing either local or general artificial sunlight treatment. High powered diathermy and high frequency apparatus are also installed.

A separate hydrotherapy department is provided in each block close to the dormitories. The main room is provided with three baths for prolonged immersion, with thermostatic control so that it is impossible for the hot water supplied to exceed a temperature of 110° to 115° F. The electric bath has no earth connections and a sinusoidal surging current of 25 to 100 volts is employed. All these baths are so arranged that a number of patients can receive individual attention at the same time. Scotch Aix, and Vichy douches are provided, as well as the latest appliances for sprays, needle baths, etc. Adjoining is a room for massage and manipulative treatment, with a dressing room off it, and in another room provision is made for various kinds of hot packs used in connection with the baths. Special care has been taken in the installation of the most up-to-date equipment for intestinal lavage on the Plombieres system, so valuable in the treatment of mental cases. The hydrotherapy department is completed by a Turkish bath installation in a separate building close to the hospital, where all forms of hot air and vapour treatments are provided.

### *The Opening Ceremony*

After the company were seated, Sir Frederick J. Willes, chairman of the Board of Control, made a statement in which he said that while the public health of the country had improved in the last fifty years, the same could not be said of public mental health and he congratulated St. Andrew's Hospital on taking such a notable step further to deal with the problem. He was especially glad that research would take a prominent place in the work of the new hospital.

The Marquess of Exeter then asked the Lord Chancellor to declare the Reception Hospital open. The opening ceremony followed and the Bishop of Peterborough (Dr. Clande Blagden) said a dedicatory prayer.

A vote of thanks to the Lord Chancellor was proposed by Mr. Christopher Smyth, chairman of the Committee of Management, and seconded by Sir Charles Gunning. The guests afterwards inspected the hospital under the guidance of the medical superintendent, Dr. Daniel F. Rambaut.

## FOOD POISONING

## MALCOLM MORRIS MEMORIAL LECTURE

THE second Malcolm Morris memorial lecture, under the auspices of the Chadwick Trust, was delivered in the Hastings Hall of the British Medical Association House, Tavistock Square, on Monday, October 17th. The lecturer was Dr W G SAVAGE, medical officer of health for Somerset, who took for his subject "Food poisoning." The chair was occupied by Sir William J Collins.

Dr Savage, after a tribute to the late Sir Malcolm Morris, whose interest in public health problems was always fresh and stimulating, began his lecture by pointing out that food poisoning must have been present from the earliest ages of mankind. Only by experience could man have learned what foods to take and what to reject. The appointment of "tasters" to kings and other highly placed persons proved that deliberate food poisoning was of very early date. But new types of food poisoning had arisen in modern civilized communities, with the necessity for conserving food for long periods and the desire of people to have their palates tickled by made-up foods or foods preserved in various ways. The simplest type of food poisoning was that in which the poison was inherent in the animal or plant eaten—for instance, the globe fish, which caused many deaths in Japan, or certain kinds of fungi, which occasioned poisoning outbreaks in this country. Again, there was the admixture, accidentally or by design, of poisonous chemical substances with the food. The risikenal spraying of apples seemed to be dangerous, for poisonous doses of arsenic had been found on apples so treated. Not very long ago there was an outbreak of belladonna poisoning in a family who had been consuming stuffed breast of mutton, the mutton had been stuffed with sage, mixed with which were a certain number of belladonna leaves.

The great bulk of food-poisoning cases, however, were due to bacteria. Dr Savage described a typical bacteriological outbreak which he had investigated in an isolated country village. A woman had purchased pig bones from the local butcher, and had used them to make brawn. As a result of eating the brawn, seventeen persons suffered from poisoning and three died. A bacillus was isolated from a fatal case, and was without doubt the cause of the outbreak. The pig from which the bones had been obtained had evidently suffered from disease, judging by one leg which it was possible to examine, and probably its disease was due to infection with the same bacillus. It was for a long time supposed—and indeed the idea still lingered—that the cause of poisoning outbreaks was the eating of food which was in some way tainted or decomposed. The common name for such cases was "ptomaine poisoning," and the term was still freely used although it was wholly incorrect. There was no such thing as ptomaine poisoning. In the first place, no ptomaines were formed in meat or other food until it was far too nasty to be eaten even by the most ravenous. Ptomaines were produced only in a very late stage of the decomposition of organic matter. Again, in practically all poisoning outbreaks there was one characteristic, namely, that in appearance, taste, and smell the food which caused the poisoning was indistinguishable from sound food. A special group of bacilli, the Salmonella group, was responsible for at least, on a rough computation, three-fourths of the outbreaks of food poisoning. These bacilli grew very rapidly in food, particularly in hot weather, but the food did not show any physical change.

One feature of poisoning outbreaks was their seasonal prevalence. They were distinctly more frequent in the summer months. On analysing a list of 200 outbreaks of which he had had experience, he found the cause to be approximately as follows:

	30 per cent
Canned foods	7
Milk	7
Milk products (chiefly ice cream and cheese)	8
Made-up meats	27
Meats less manipulated (for example, stuffed)	4
Fresh meat	16
Fruits and vegetables	4
Other foods	4

As during a part of this investigation he was specially looking for instances of canned-food poisoning it was possible that the proportion set out under that head was rather higher than the average, but the point is that 72 per cent of the outbreaks were due to foods which had been man-handled in some way or other, such as chopping, mashing, mincing, or mixing, such as chopping, mashing, mincing, or mixing. A great many foods of this type had been heated up and slowly cooled, a process which offered considerable opportunities for contamination, especially if the cooling took place in dirty surroundings. He instanced an ice-cream outbreak, in which the producer had made five gallons of ice-cream from milk, cornstarch, sugar, and flavouring matters, all the ingredients being good but, after boiling, had left the mixture to cool in an outhouse yard before freezing. As a result there were 400 known cases of poisoning, though, fortunately, only one death. The investigation showed that the cooling mass must have been infected by bacilli which had had time, before the freezing took place, to multiply to large numbers. The Salmonella group had one property which it shared with no other group of micro-organisms—namely, that though the organisms were rather vulnerable, the toxins they produced were heat-resistant. Food could be boiled for an hour, and the poisons were not destroyed. After a brief reference to botulism, Dr Savage passed to a discussion of the prevention of food poisoning, poisoning, instead of being a sort of general infection of food with bacilli, was a very specific infection. Prevention therefore resolved itself into a determined hunt to find the sources from which these food poisoning bacilli came. The Salmonella were not natural inhabitants of the intestinal tract of man or animals, but they were found in diseased animals, and possibly a number of the outbreaks were due to diseased animals being used for food. More often, however, these bacilli got on to the food from outside sources, connected with the handling such foods received, either in the preparation or the storage. Sometimes infection might be carried by flies or by vermin in slaughter houses, dairies, and similar places. The first principle of prevention was to find the reservoirs of these bacilli and destroy them. The second principle was scrupulous cleanliness in the food trades, especially the enforcement of Section 12 of the Meat Regulations of 1924. The third line was to do much greater care in the treatment of made-up foods. There was urgent need for the registration of premises where made-up foods were produced, in the same way as bakeries and the like. The individual was practically defenceless, except, of course, that he would do well to practise strict rules of cleanliness in relation to food and to obtain his food from reliable sources.

A vote of thanks to the lecturer was proposed and seconded respectively by Sir StClair Thomson and Sir Harold Morris, K.C., the latter the son of the man in whose memory the lecture was founded.

## England and Wales.

## NEWCASTLE-ON-TYNE THE NEW SESSION

THE formal opening of the winter session at the University of Durham College of Medicine, Newcastle-on-Tyne, took place on the evening of October 11th. Dr Thomas Oliver, president of the college, took the chair and in opening the proceedings paid a tribute to Mr J. Brunton Angus, emeritus professor of surgery, and Dr H. E. Armstrong, the first lecturer in public health at the college, of whom obituary notices appeared in our last issue. The introductory address was given by Dr John Rose Bradford, President of the Royal College of Physicians of London, whose subject was "The study of medicine." After remarking that, in his experience, it was very rare for students to regret having chosen medicine as a career, he asked why the study of medicine should prove so satisfactory to its disciples and yet not lead to the extreme narrowing of mental outlook sometimes met with at other vocations. The reason for this was twofold—in the first place, medicine was a branch of natural knowledge.

secondly, its practical applications were so numerous and ever increasing that there was scarcely any department of human activity that did not enter into close relations with medicine. The student was thus not only brought face to face with problems of surprising scientific interest, but of necessity came into close relation with his fellow creatures, at times when the artificialities of life were broken down and human nature was faced with realities. Much of the criticism of the medical profession by intelligent laymen was justified by the tendency of some of its members to lay down the law on various matters as though their conclusions were warranted by facts instead of being mere opinions. This tendency to dogmatic utterances was one to be guarded against. Another point made by Sir John Ross Bradford was the need for those embarking on a medical career to develop a correct attitude of mind by correct methods of study. The vote of thanks was proposed by Professor Thomas Beattie and seconded by Professor Stuart McDouald.

#### A CONTRIBUTORY SCHEME FOR BIRMINGHAM

In the *Birmingham Post* of October 8th considerable space is devoted to an account of a new "contributory scheme" for hospital benefit which it is intended to launch in that city in January, 1928. Despite the space given to the project the account is not very clear, at least not in what we would regard as the essential features of such a scheme. So far as it is now set forth the plan is this. The scheme is to be organized by the Saturday Fund as the collecting agency, this body will have special representation on the central committee. Contributors will be required to pay a minimum of twopence a week. The employers will be asked to pay an amount to the fund equal to one-fourth of that contributed by their employees. There will be a hospital guild for the purpose of gathering contributions from those who are outside the normal operations of the collecting scheme, so that in the event of such contributors requiring treatment they will not be asked to pay for their maintenance while in hospital. It is hoped that those who are over the income limit will subscribe or make donations to the scheme. The hospitals will be open without charge to the very poor who are unable to join the contributory scheme. Others whose income is limited and who are accepted for hospital treatment under the present practice of the hospitals will be eligible for free treatment if they belong to the scheme. Contributors not considered eligible for free treatment may be called upon to make some additional payment to the funds of the hospital in accordance with the present practice of the hospitals. "It is hoped each hospital will make a maintenance charge for those patients who are non-contributors and who could afford to pay twopence per week." Hospital and convalescent home benefits will be extended to actual dependants of contributors. The basis of distribution of the funds will be the cost of maintenance of patients other than those provided for by grants from public authorities and private ward and other fees. Eventually it is anticipated that the whole of the net cost of the maintenance of contributing patients will be met out of the contributory scheme. It is intended that the districts immediately adjoining Birmingham shall be linked up with it in this project.

The scheme contains some novel features which call for careful consideration by the medical profession, and we have no doubt that the executives of the Divisions of the British Medical Association in the areas to be included will investigate the matter fully. It would appear that there is to be an income limit for what may be termed average contributors, but its amount has not so far been disclosed. The average contributors to the scheme when admitted to hospital will receive free treatment. Our contemporary writes:

Among the signal advantage of the new scheme is that it will enable the hospitals finally to abandon the inconvenient and unpopular ticket system. Incidentally it will also imply the abandonment of works collections in aid of particular hospitals. It will increase certainly to an appreciable extent and probably largely the number of those who hold that by virtue of their weekly contributions they establish a right to hospital treatment in case of sickness.

There are two features of some novelty in this scheme. One is that the promoters appear to intend that those who are not properly of the economic status included within the income limit (whatever that may be) may yet be admitted members of the scheme, but if and when admitted to hospital will be required to make some payment to the hospital over and above that which the hospital will receive from the fund on their account. Further, the promoters of the scheme desire the hospital authorities to require payment from persons admitted to the hospitals who are not members of the scheme and who are deemed to have been capable of making the minimum payment of twopence a week. Throughout the account of the scheme there is not a word or hint of the bearing all this will have upon the economic status of the medical staffs of the hospitals. In some of the paragraphs phrases are used which if taken literally, would render the medical staffs of these hospitals liable to give their services gratuitously for the patients who pay in part or in whole for their hospital treatment, for it is written: "The basis of distribution of the funds, will be the cost of maintenance of patients" (the italics are ours). In yet other places the wider term "treatment" is used. Another novel feature of the scheme is the association of employers in a financial obligation to supplement the contributions of their employees. It appears that the first suggestion was that this amount was to be one third that contributed by the employee, but that it was afterwards settled at one-fourth.

Contributory schemes are forms of insurance. They are just as much insurance as the insurance of one's house against fire. There is a tendency in some quarters to attempt to disguise this fact by a haze of philanthropic zeal on behalf of the hospitals. Such zeal is right and laudable, but it should not be allowed to blind the critical eye, so that it fails to scrutinize the details of the policy of insurance which is enacted under the guise of such contributory schemes. A lack of care in the initiation of these schemes may mean a world of trouble later on and possibly strained relations between the authors of the schemes, the hospitals and the contributors, which might be avoided by a little cool criticism at the outset.

#### NEW ISOLATION HOSPITAL AT SOUTHPORT

Sir George Newman opened a new isolation hospital at Southport on October 15th, this being the first building of the kind erected in England since the war. The hospital contains two scarlet fever wards, of twenty-two and twenty beds respectively, a diphtheria block of twenty beds, an observation block of eight beds, and a discharge block of two beds. There is, in addition, a tuberculosis pavilion of twenty-two beds, and shelters providing accommodation for eight patients. Should it later be found necessary, it will be possible to erect an additional fever block in the hospital enclosure and also another tuberculosis pavilion. The estimated cost of building and equipping the hospital was £81,000, and an additional sum of nearly £16,000 was required for the purchase of the land. Sir George Newman referred to his recent visit to America, and said that he believed the Southport Isolation Hospital must be one of the finest of these institutions in the world. In the course of his speech he emphasized the importance of securing the friendly co-operation of private practitioners in the prevention of disease, and paid a high tribute to those engaged in the health insurance service. Early diagnosis and prompt notification of such infectious diseases were, he added, exceedingly necessary if the public health was to be maintained and improved.

#### SURGICAL INSTRUMENT MANUFACTURERS' ASSOCIATION

The annual dinner of the Surgical Instrument Manufacturers Association was held at the Holborn Restaurant on October 14th, under the chairmanship of Mr Ernest W. Mayer. The toast of the association was proposed by Mr P. C. May, who referred to the valuable work done by the association during the past year. Sir John Corcoran, director of the National Union of Manufacturers, remarked on the fact that the association included in its membership more than 90 per cent of the manufacturers engaged in this branch of production. Its application

Industries proceeding had been rejected by the Board of Trade on the ground that the industry was not of substantial importance and that foreign competition was not exceptional, but Sir John Corcoran said that when he was at the War Office during the war he never heard it suggested—and in the circumstances of that time it would have been unthinkable—that the industry was not substantial or of national importance, while as to the second point, there was a large foreign importation, and it ought not to be necessary for the association, in order to get a safeguarding duty, to prove that it was exceptional. The association was also bringing forward an application for the marking under the Merchandise Marks Act of surgical instruments on their importation. He thought it was wise to press for this, because if goods were imported unmixed it was a matter of extreme difficulty, in view of the wiles of the importers, to prove that they were of foreign origin once they had been distributed. Mr Cecil Rowntice, F.R.C.S., who spoke as one of the guests, said that the industry might truly be described as a philanthropic one, especially since the advent of stainless steel, for instruments so made seemed as if they would last for ever. Mr L Ferris-Scott, Financial Secretary and Business Manager of the British Medical Association, complimented the manufacturers upon the imagination they invariably displayed, and said that he knew how fully the medical profession recognized the debt it owed to the instrument makers of the country.

#### ROOM DISINFECTION IN INFECTIOUS DISEASES

In his report for 1926 Dr R H H Jolly, medical officer of health for the county borough of Wolverhampton, comments upon disinfection in connexion with infectious diseases. While agreeing that the value of steam disinfection of the bedding and wearing apparel of these patients is unchallenged, he expresses the doubt whether anything is gained by scaling up rooms and burning formalin lamps in them, in view of the uncertainty whether the infecting agents of acute contagious diseases can survive for many hours on furniture, walls, or carpets, and the probability that the disinfectant liberated in the room is unable to destroy the bacteria. He states that the abandonment by various health departments of room disinfection for scarlet fever and diphtheria has not caused any adverse results, thus supporting the view that direct transference of the infecting agent from one person to another is the usual method of the spread of contagion. Dr Jolly adds that, since the use of scabietinal antistreptococcal serum became a routine measure in all early cases of scarlet fever, it has been found possible to reduce the length of the stay in hospital of these patients by nearly a fortnight without increasing the risks of infection after discharge. He thinks that the serum has also been particularly valuable in the treatment of severe cases. Only a few patients with septic infection were admitted to hospital during the year, but when the serum was administered early in this condition they made quick recoveries and their convalescence was uneventful. With a view to providing better accommodation for the isolation of doubtful cases, or of those with a double infection the erection of an isolation ward containing ten single cubicles is proposed.

#### CENTRAL MIDWIVES BOARD

The Central Midwives Board for England and Wales met on October 6th, when Sir Francis Crumpney (president) was in the chair. A communication was received from the Society of Apothecaries of London, stating that it had nominated Dr Thomas Vincent Dickenson to be its representative in lieu of Mr Charles Sangster, and a vote of condolence with Mr Sangster's family on his death was adopted. In reply to the medical officer of health for Lindsey the Board expressed the opinion that it would not be possible for each practising midwife to have a pair of callipers, and that the local supervising authority should keep a stock of these instruments for use by midwives when required. In reply to an inquiry from the medical officer of health for Surrey, the Board stated that "in all cases the person actually conducting a confinement should sign the form of sending

for medical help." The Board approved for one year the scheme of the Birmingham University for lectures to be delivered to pupil midwives in the area. The following institutions were approved as training schools: Birmingham Hospital, Mill Road Infirmary, Liverpool Newton, Widra Maternity Hospital, Patel, Bombay. It was reported that applications from midwifery authorities in various parts of the British Empire for the conclusion of reciprocal arrangements between them and the Board had been received, and the Approvals Subcommittee was given power to co-opt one or more additional members for their consideration.

The amendment of the Registration of Nursing Homes Bill, to the effect that non-county boroughs and urban districts employing whole-time medical officers of health should be the registration and inspecting authorities for nursing homes (including maternity homes) in their district, was considered, and the Board adopted a resolution strongly deprecating the amendment in so far as maternity homes were concerned, and instructed the secretary to advise the Minister of Health and also the County Councils Association of this opinion.

## Scotland.

#### ABERDEEN UNIVERSITY THE NEW SESSION

The winter term of the Faculty of Medicine of the University of Aberdeen opened on October 11th. Professor A W Mackintosh welcomed the students, and in recognition to the resignation of Professor McWilliam from the chair of physiology after forty-one years, said that they were glad to know that he was still to be with them for a few months. The resignation was a tremendous blow to them all. They were proud to have had such a distinguished scientist and lecturer amongst their alumni and professors, but he was sure that their chief and most cherished memory of Professor McWilliam would be of the man himself, who was ever a kindly and helpful friend, most lovable and modest to a degree. Professor Mackintosh, in referring to the joint hospital scheme at Lossisthull and the town council's scheme of extension at Oldmill and the City Hospital, paid a warm tribute to the Lord Provost for his noble efforts in the great cause, and expressed his conviction that the great endeavour would be brought to fruition. While a whole-hearted believer in the voluntary hospital system he was equally strong in the belief of the need for co-operation with the hospitals that were statutorily under the local authority. He considered that it would be an incalculable benefit to the sick if some working scheme could be arrived at, and he was glad to know that a movement towards that ideal was under consideration now in Aberdeen. Professor Mackintosh subsequently delivered his opening lecture dealing with the lives of Thomas Linacre (1460-1524), Francis Adams (1724-1861), and Charles Creighton (1847-1927).

#### NEW COMBINED HOSPITAL AT ABERDEEN

The Woodend Hospital at Aberdeen, which is to be utilized by Aberdeen municipal public health services, was opened on October 15th by Sir John Gilmour, Secretary of State for Scotland. Lord Provost Lewis and the magistrates of the city, as well as members of the Aberdeen Parish Council, were present. Sir John Gilmour said that the present was the first example of the co-ordination of hospital services to take place in Scotland. It was no matter to bring about uniformity in services, whether public or private, for special services developed as time went on under different conditions. There must come, however, when overlapping and wasteful expenditure arose. The example now given by Aberdeen was an instance of the way in which harmony might be attained through wise leadership, and this had been achieved through the helpful and capable guidance of the Lord Provost of the city. The scheme was fully approved by the Scottish Board of Health. A wide appeal had been made for public help, and the project had been received by the people, its development would be watched.

with the greatest interest. He was a strong supporter of the voluntary hospitals and believed that in Scotland they would not be abandoned without great misgiving but so was equally certain that there ought to be the closest co-operation between the great national services, the town and parish councils, and the voluntary hospitals.

#### MEDICAL GYMNASTICS

A congress the first of its kind was held under the auspices of the Chartered Society of Massage and Medical Gymnastics in the Rankin Hall, Glasgow, on October 6th and 7th. Mr. Matthew White, F.R.C.S., who presided at the opening, mentioned that out of 6,000 members in the society, 450 were resident in Scotland. Mr. Alexander MacLennan, M.B., C.M., delivered an address on crippling deformities in children. Mr. G. H. Stevenson, F.R.C.S., delivered a lecture on rest and posture in treatment in which he remarked that continuity of treatment was an important factor during the whole twenty-four hours whether the patient was awake or asleep. Correct posturing sleep should be prescribed for adults as well as children. Demonstrations were given upon such subjects as sling exercises for re-education in paralysis, and upon English and Scottish country dancing. The meeting was continued in Edinburgh on October 8th. A visit was paid to the massage department of the Royal Infirmary, where a demonstration was given by Miss Mann, who showed the treatment and exercises adopted by masseuses for stiff joints. In a lecture on foot conditions, Professor John Fraser dealt with the peculiarities of the arch of the foot with various congenital and acquired deformities, pointing out what could be remedied by massage and what could not. In the afternoon the annual meeting of the Chartered Society of Massage and Medical Gymnastics was held in the Royal Infirmary. Sir Cooper Perry, M.D., presiding. A proposal to prepare for publication a kind of directory of masseurs, together with their addresses, qualifications, and forms of treatment, was favourably considered. The meeting also considered the question of applying for State registration for persons practising massage.

#### PROPOSED REFRACTION HOSPITAL IN GLASGOW

A meeting of opticians was held in Glasgow on September 21st to consider a proposal which had been made for the establishment of a "Refraction Hospital" on lines similar to that of the London Refraction Hospital. Mr. R. Jackson presided and referred to the need for such an institution in Glasgow in order to deal effectively with the special needs of the necessitous poor. Speaking of the need of training for students in this matter, he mentioned that some 400 qualified opticians had gone through the course of the hospital in London. It was reported that the provisional committee, which had already been appointed, had received £380 and considered that the expenses of the first year would not exceed £250. The proposed objects of this scheme are to provide voluntary service for ophthalmic training, to form an educational centre for qualified opticians and students to furnish facilities for the study and recognition of abnormal and pathological conditions of the eye, as well as providing special clinical instruction for opticians and finally to promote research in optical refraction. The meeting unanimously decided to proceed with the scheme and a committee of opticians from various parts of Scotland was elected to secure premises in one of the poorer districts of Glasgow.

#### HEALTH OF DUNDEE 1926

Dr. W. L. Burgess, medical officer of health for Dundee, in his annual report for 1926 states that the population of the city was estimated at 170,060. The birth rate per 1,000 was 21.9, the corrected death rate 14.8, the infant mortality rate 103, the general tuberculosis death rate 1.12, and the pulmonary tuberculosis death rate 0.81. Tuberculosis death rates are the lowest yet recorded, mark genuine progress. The number of new houses completed during the year was 744. This is a "record" for the city. It is estimated to be considerably in excess of the normal annual increment, and is therefore a substantial

contribution to the reduction of the housing shortage. Of the 744 houses 389 were erected by the corporation and 355 by private enterprise. The problem of slum clearance still offers difficulty. The view is expressed that a two-roomed house may be quite healthy if the number and sex of its occupants are controlled. Re-housed slum dwellers on the whole keep their new houses well. The employment of women rent collectors with experience in house management is recommended in the public interest. In the month of June complaints were received from the west end of the city of a plague of mosquitos. It was traced to a pond in which larvae abounded. The pernicious insect was the common gnat. The pond has been filled up. The personnel of the meat inspection staff is now complete and the number of detections of disease among animals killed at the slaughter house has doubled during the year. Tubercle bacilli were not recovered from any of the twenty-four specimens of milk submitted for examination. Of the 7,500 gallons of milk distributed daily in Dundee more than 50 per cent is pasteurized. Dr. Burgess, under the present conditions of milk production and distribution, is strongly in favour of pasteurized milk and encourages its use. In Dundee there is little certified or Grade A (tuberculin tested) milk on sale, and its price in any case would be prohibitive for many. Pasteurized milk on the other hand, is sold at the same price as raw milk, and may be obtained in bottles. Of sundry recent milk borne infections in the city not one has been traced to pasteurized milk. In an extensive outbreak of food poisoning due to milk occurred in the city in August. The causative organism was *B. enteritidis* (Gaertner), and the source of infection was promptly discovered, was a cow at a dairy farm suffering from enteritis. The Gaertner bacillus was demonstrated in the discharges of the cow, in the milk distributed, and in the excreta of the sick, and the specific immunity response was given by the blood of convalescents. The cow died of its enteritis, but all the infected persons recovered. Of 1,084 persons immunized against diphtheria fourteen were later suspected of suffering from the disease. Of this number two were undoubted cases, the rest were dubious, negative, or carriers. Testing and immunization on a minor scale were carried out in scarlet fever. Of 415 cases of primary and influenza pneumonia nearly one-half were treated in Dundee Royal Infirmary. Nine cases of encephalitis lethargica were notified, all in late stages.

#### SCIENCE AND MEDICINE

The Royal Medical Society of Edinburgh began its 191st annual session on October 14th, when Dr. D. Noel Paton, F.R.S., professor of physiology in the University of Glasgow, delivered an inaugural address on the relationship of science to medicine. Dr. W. R. Russell, senior president of the society, who occupied the chair, reminded the audience that the Royal Medical Society had been closely connected with medical education in Edinburgh for nearly two hundred years almost since the foundation of the Medical Faculty in the University. The society had had much to do in creating the reputation of Edinburgh as a medical school. Professor Paton said that science meant the pursuit of knowledge while medicine was the application of knowledge to the diagnosis, treatment, and prevention of disease. Every good doctor must in addition be possessed of certain human characteristics, including kindness, unselfishness, and sympathy. Two further qualities were also necessary—the power of keen observation and the faculty of reasoning from what was observed. The main object of the study of preliminary scientific subjects was to give the student this training in observation and reasoning. He believed that the science which above all others afforded this training was physiology. The medical man must know how to investigate the action of different structures in his patient and he must know whether their action was normal. Further this knowledge must be real and practical, not acquired from books or lectures. The qualities required either by the scientific investigator or by the clinician might be enumerated under five heads. First there was curiosity with a perpetual asking of what, why, and how, and how similar to that possessed by every healthy and intelligent child.

Secondly, there was imagination to see various possibilities and where they led, with the power of employing theories as guides. Thirdly, determination was important, and these three were probably inborn characteristics. The last two qualities were the critical faculty by which the value of evidence could be estimated and, finally, the faculty of observing honestly and without preconceived ideas.

## Ireland.

### RESIGNATION OF PROFESSOR PEARSON OF CORK

PROFESSOR CHARLES YEIVERTON PEARSON, M.D., M.Ch., R.U.I., F.R.C.S. Eng., is resigning the chair of surgery at University College, Cork, on attaining the age limit. He has held the position for many years past, to the great advantage not only to the University, but to the whole medical profession in the South of Ireland. His position as the leading surgeon was recognized some years ago by the appointment as honorary surgeon to the King in Ireland. We understand that Professor Pearson is not retiring from active work, and all his friends and former pupils will wish him a long continuance of his useful life.

### LOCAL GOVERNMENT IN NORTHERN IRELAND

The report of the Departmental Commission on the Local Government Administration of Northern Ireland was presented to the Parliament of Northern Ireland on October 13th. The Commission was a large one, it contained about thirty-five members, including several medical men and several women. The doctors were Professor R. J. Johnstone, M.B., F.R.C.S., M.P., who was chairman, Lieut.-Colonel Dawson, O.B.E., M.D., David Gray, M.A., M.D., Professor J. A. Lindsay, M.A., M.D., Dr. J. M. McCloy, Dr. W. McLouman, Dr. H. S. Morrison, D.L., M.P., and Alderman J. D. Williamson, M.D. There are forty-seven recommendations, but there are also several reservations by individual members. These recommendations deal with the abolition of boards of guardians and changes in the poor relief services, which it is recommended should be put on a county basis, under county council control. The individual recommendations will be noted later.

### COMMISSION ON THE RELIEF OF THE SICK AND DISTITUTE POOR

In the course of its report the Commission on the Relief of the Sick and Destitute Poor states its conviction that the schemes, both positively and in their administration, have in some counties, particularly the larger, where the distances are considerable, operated prejudicially in the interests of the poor, while the saving in cost has been negligible. The classes that should not be returned in the county homes, and for which other provisions will have to be made, are unmarried mothers, married mothers, children, and mental defectives. Even if reserved for the aged and infirm poor and chronic invalids, the county homes, with one or two exceptions, require much structural alteration and improvement before they can be considered as coming up to the standard of comfort required. Discussing the provision of hospital accommodation the report states:

The Commission is in full accord with the policy of establishing without overlapping or duplication, in the most accessible centres of population, public hospitals where the poor are likely to find the medical assistance available to obtain modern and skilled treatment in surgery and medicine. The normal provision in each county or county health district would be one fully equipped central hospital, with district or cottage hospitals as auxiliaries where distance and population justified such auxiliaries. Given a hospital which was established for itself a record of efficient and sympathetic administration, and to which admission could be readily obtained, distances of from twenty to twenty-five miles will not deter the poor from availing of it in areas where there are good roads and modern means of transport. In some counties the institutional accommodation provided for the sick falls far short of what the county scheme contemplates. The counties chosen for the county hospitals are, as a rule, suitable, centres chosen for the county hospitals are, as a rule, suitable, centres chosen for the county hospitals are, as a rule, suitable, but the hospitals themselves are not, in some instances, up to a reasonable standard, nor is the accommodation sufficient, while in others the development is taking place on lines that are not

consistent with the general policy of complete severance from ordinary poor relief.

The county hospital should be an institution under one control in which both medical and surgical cases are treated. The arrangement in several counties under which surgical cases are treated in a county surgical hospital and medical cases related to the wards of the county home the Commission do not regard as satisfactory. Most of the district hospitals are situated in old workhouse buildings and while exception cannot be taken in every case to this, the Commission think that unless they can be effectively cut off from the unoccupied portions of these old buildings, the location will not ultimately prove satisfactory, and modern small hospitals will have to be provided. The accommodation for cases of infectious and contagious diseases does not appear to be inadequate except in the counties of Galway, Mayo and Inverness, but in several other counties it is, for reasons indicated in the report unsuitable.

Whilst recognizing the difficult problem presented by the advanced cases of tuberculosis the Commission does not think the county home is the proper place for them, or that they should be admitted to the district hospitals unless they can be completely isolated. The accommodation in some of the dispensaries visited was unsuitable and the furnishing of the poorest description. The order and cleanliness in a number were very bad and, generally speaking, the standard of comfort was low. It is essential that the accommodation should be clean, comfortable and well equipped, and sufficient to ensure absolute privacy for a complete examination should such be necessary.

The inspections of dispensaries by the Local Government Department's inspectors should be carried out without notice. Every encouragement should be given to the dispensary medical officers to look upon the hospitals as a necessary complement to the dispensaries. In support of the recommendation for surprise visits by inspectors the statement is made that the poor, as a whole, are very slow to make complaints, but because no complaints are made it does not follow that there are no grounds for complaint, and conscientious inspections very often oblige the necessity for complaint, and give confidence to the poor.

Dr. Hennessy, one of the members of the Commission, dissents from the opinions of his colleagues on this question, and submits a searching criticism of the defects inherent in the Poor Law medical service.

While recognizing that it is possible for a Board of Health, under a capable and businesslike chairman and with the help of committees, to work the administrative machine efficiently, the Commission is inclined to the view that in actual practice the Boards are not able to exercise the supervision which their institutions, officers, and services require. The Commission is unable to formulate any plan which, by merely altering the constitution or methods of procedure of the Boards, would be calculated to lead to more efficient administration. The alternative it recommends is the abolition of the Board of Health and the assumption by the county council itself of the control of poor relief, working through a paid official in entire charge of the Poor Law services of the county, like the general manager of a company under the control of a board of directors. Dealing with mental hospitals, the report states:

The accommodation for the insane poor in the district mental hospitals (including the auxiliary mental hospitals) is either fully occupied or insufficient or unsuitable in all but three instances (Kilkenny, Letterkenny, and Portlaoighle Mental Hospitals). The Boards of Health should be encouraged to avail themselves of the recommendation for mentally defective children that now exists. The Commission recommends that as an inducement to send such children to an approved institution a grant equal to half the such children to an approved institution should be made. Subject to the condition that the child can benefit by the training, the Board of Health should be empowered if it think fit to join with the parents of a mentally defective child in paying the expenses of maintenance in an approved institution. No child should be retained at the public expense in an approved institution beyond the time when improvement in his or her condition cannot be effected. Approved institutions for defectives should be visited and reported on by the inspector of mental hospitals. The Commission proposes that without lessening the safeguards against improper detention certain defects in the present procedure for admission should be remedied. The Commission recommends that in the case of poor persons who become insane, and whose relatives are not in a position to pay for the means of conveyance or for the medical certificate, it should be the duty of the home assistance officer to arrange for examination, certification and transfer to the mental hospital. The Commission anticipates that with the alternative procedure it is able to meet the necessities of poor persons the number of commitments as dangerous lunatics under the Lunacy Act, 1867 will be considerably reduced. The Commission recommends that the law should relieve police commissioners' medical practitioners and all persons giving certificates and making orders in connection with the reception of patients into mental hospitals from liability to legal proceedings if they act in good faith and with reasonable care. The power to discharge patients on probation should be more freely used, and the maximum period of absence on probation extended.

## Correspondence.

### CATARRHAL VACCINES

SIR,—The figures supplied by the Lton medical officers (October 15th p 702) are of considerable interest, and at first sight suggest that mass inoculations in schools are not of much, if any, value. But may I suggest that there is a fallacy?

The anticatarrhal vaccines cannot be expected to prevent epidemic influenza—at least I have never hoped for such a result. I firmly believe that true epidemic influenza is at present beyond our control. What the ardent advocates of such vaccines does believe is that they can and do, diminish the incidence of the endemic cold and catarrh which is the scourge of adolescent communities. The test of complications which is, in my opinion, a much more reasonable guide to the efficacy of vaccines, is certainly not in favour of them, so far as the Eton figures go, but the epidemic was mild, and the total number of complications very small.

My own experience of a rather similar epidemic in January is as follows. The epidemic was clearly of a more severe type than that at Eton, but in its incidence, length of illness and number of complications and their severity, the advantage lies with the inoculated. I have also included figures relating to colds and cases of pyrexia of unknown origin (that is feverish chill) which occurred later in the term, after the influenza epidemic had ceased.

#### Haileybury College Inoculation 1927 Non inoculated (315)

Influenza	67=21.27%
Days lost	890=Av 13.2
Complications	26
Pneumonia 5, bronchitis 6, otitis 6 (4 abscesses), frontal sinus and maxillary antrum (op) 1, acute rhinitis 6, enteritis (haemorrhagic) 1, adenitis 1	

Pyrexia of unknown origin	10=3.1%
Days lost	95=Av 9.5
Complications	6
Bronchitis 2, otitis 3 (1 abscess), acute rhinitis 1	

Cold (6 a second time)	71=22.5%
------------------------	----------

#### Inoculated (215) AC 95 PS 120

Influenza	34=15.8%
Days lost	374=Av 11
Complications	9
Bronchitis 4 (1 AC, 3 PS), otitis 1 (PS), adenitis 4 (1 AC, 3 PS)	

Pyrexia of unknown origin	5=2.3%
Days lost	55=Av 11
Complications	4
Bronchitis 1 (AC), otitis 2 (abcesses), 1 PS, 1 AC, adenitis 1 (PS)	

Colds	29=13.5%
(AC 9=9.4%, PS 20=16.6%)	

Days lost by the 34 inoculated influenza cases	65=Av 9
7 AC cases (71%)	309=Av 11.5
27 PS cases (22.5%)	

AC = Park-Davis's Anticatarrhal vaccine PS = Public School vaccine

I wish more school medical officers would take the trouble shown by the Lton doctors to try the effects of vaccines and publish their figures. It is only by the accumulation of figures from various sources that we can hope to get anything in the nature of proof. Those who like myself, do believe in vaccine treatment for colds and catarrh may be wrong and mistake *post hoc* for *propter hoc*, but meanwhile it seems to offer the only method of diminishing those common minor complaints which seriously affect the schools' welfare, far more so than the infectious epidemics. The public school vaccine collected through the activities of the Medical Officers of Schools Association prepared in St Mary's Hospital Laboratories and issued by Messrs Parke Davis and Co. is now on the market and a circular is being issued to all school doctors inviting them to make use of it and record their results—I am, etc.

L. R. LEMPTIEFF  
Medical Officer Haileybury College.

### DENTAL RADIOGRAMS IN DIAGNOSIS

SIR,—Permit me to draw attention to a practice which appears to be growing and is, I venture to think, prejudicial to all concerned.

It is this: A doctor thinking that the condition of a patient's teeth may have a bearing on the illness sends him to a radiographer of his own choosing. On the strength of his own or the radiographer's interpretation of the resulting radiogram—often not too clear—he makes a diagnosis, possibly prescribes treatment, and either requires the patient's own dentist to carry it out or very frequently, sends him to someone else of his own selection. Surely this is wrong.

Dental radiograms are a very valuable aid to diagnosis, but only an aid, and no substitute for clinical examination. They are often invaluable in revealing unsuspected trouble, more often still in affording ocular and convincing proof of what the dentist already knows or suspects; but, on the other hand, there may be serious sepsis without any sign of it in the radiogram, negative evidence cannot be relied upon.

Moreover, to be of value they must be really good, and to produce good dental films requires considerable practice. With certain brilliant exceptions the dentist who takes his own usually attains to a higher level of perfection than the general radiographer. Far too many reports are made upon skiagrams so imperfect that no safe deductions can be drawn from them.

Having obtained good films they must be correctly interpreted, often no easy matter and here again the dentist is more likely to be successful than the medical man, or the radiologist in whose report the doctor usually puts implicit faith.

As examples of the gross errors easily made I may mention a case where a patient was recently told by his doctor that an upper wisdom tooth was diseased and must come out, the "tooth" in question being the coronoid process of the mandible and the frequent condemnation of lower premolars as the subjects of apical sepsis by reason of the proximity of the inferior dental foramen to their roots.

It is obviously unwise to depend upon the shadow for diagnosis, and entirely ignore the substance. No dentist would rely solely upon radiograms apart from clinical examination and the clinical history. Were he limited to one or the other he would certainly choose a careful clinical examination.

It is not uncommon for a patient to come to a dentist with films taken at the request of his doctor and instructions that certain teeth are septic and to be removed, while others much worse have passed unnoticed.

It is not only discourteous to ignore the patient's own dentist but shortsighted because if a careful man he will have a recorded history of the mouth which may prove of the utmost value. The reasons why he is so often ignored by the doctor when a diagnosis is to be made would appear to be that the doctor mistrusts dentists in general (or, possibly with good reason that one in particular), while he overrates skiagrams as a source of accurate and complete information, and fails to realize that their interpretation is a matter in which the knowledge and experience of the dentist and his clinical findings are of the utmost value, with the assistance of the radiologist in case of difficulty.

Surely the correct course is to refer the patient in the first instance to his own dentist if he has one for a report, with skiagrams on the condition of the mouth. If for any reason this report should not inspire confidence, a second opinion should be sought. In this way the patient's best interests would be served, and no one would have cause to complain.

The facts are that the average doctor has very little knowledge of teeth and the average dentist very little knowledge of general pathology, so that only by their close co-operation can the patient derive the maximum benefit—I am, etc.,

London W.1 Oct 12th.

### "THE HISTORICAL ASPECT OF QUACKERY"

SIR,—In a recent address I made a five-line reference to Hahnemann and a three-line reference to the followers of Abrams. These short references have provoked nearly five columns of correspondence, and since I naturally dread anything in the nature of a geometric progression in polemics, I will try to answer my critics as briefly as possible.

#### (1) Hahnemann

Dr Juhn objects to my statement that Hahnemann established a dogmatic faith even more absurd than the orthodox traditions that he combated. The particular absurdity that I had in mind was not the doctrine that like cures like, but the belief in the efficacy of infinitesimal doses.

Hahnemann taught (*Organon*, 1833 edition) that the dosage of preference for drugs was the thirtieth dilution, which means a concentration of one part in  $10^{10}$  parts. This represents a concentration of one molecule of the drug in a volume of solvent nearly equal to a sphere of which the great circle is represented by the orbit of the planet Mercury. Obviously the chances are practically infinite against any dose of this dilution containing a single molecule, atom, or election of the drug.

The belief that drugs in these dilutions can produce any effect must appear absurd to all who accept the atomic theory of matter. If the homoeopaths reject the atomic theory they escape the arithmetical difficulty that I have indicated, but they ought to make it clear that they are opposed, not merely to orthodox medicine, but also to the chief basic theories of chemistry and physics.

#### (2) Quacks and Others

I agree with Dr Reid that the definition I gave of the term "quack" excluded those men who have been instructed in medical science but have forsaken it in the search for universal cures. Medical history records a continuous succession of such dissenters from inductive science, but unfortunately I know of no simple generic term by which to describe them.

#### (3) The Doctrines of Abrams

Sir James Barr has written a criticism of myself and my paper that I will try to avoid copying either as regards length or style.

The greater portion of his letter consists of abuse so vague as to be unanswerable, but he does make the definite statement that I seem to be "utterly incapable of accurately recording a historical fact." No one with any sense of responsibility would make a serious charge of this nature without adducing proof. Sir James Barr's letter fills four columns, but the only error of fact that he suggests is as follows. He says that in a former paper I stated that Perkins's tractors were made of wood and that I now say they were made of metal. I can only recollect mentioning these tractors in one paper<sup>1</sup> and there I twice stated that the tractors were metallic. I did, however, mention some imitation wooden tractors that were prepared and used by opponents of Perkins in order to show up this silly delusion. The whole point is rather trivial, but it does illustrate Sir James Barr's standards of accuracy in controversy.

I gather from Sir James Barr's letter that he thinks I have misrepresented the doctrines taught by Abrams and adopted by his followers. Now my only reference to this matter was the sentence "The followers of Abrams believe that all diseases can be both diagnosed and treated by means of two boxes containing some simple electrical apparatus."

I cannot see that Sir James Barr or Dr Reid have shown any inaccuracy in this statement. The statement describes the nature of the boxes and their alleged powers. As regards the nature of the boxes, Sir James Barr in his letter says that the curative box, the oscilloclast, is a nonderiving machine, whilst in a former paper<sup>2</sup> he described the principal component of the diagnostic machine as follows: "The rheostat or ohm meter is a specially graduated resistance coil." There can be no

doubt, therefore, that the boxes contain electrical apparatus, and the apparatus in the boxes that I have examined appeared to me to be of a relatively simple character.

As regards the powers of the boxes, I deliberately understated the claims made by their advocates. Sir James Barr has described how he could determine not merely the diseases of a patient, but also the sex and race, without ever seeing the patient, but simply by testing a drop of blood or a specimen of handwriting in the diagnostic machine of Abrams. He actually gave details of the diagnosis of cancer as an example of his technique. I have not seen or heard of any recantation of these opinions and therefore, as regards diagnosis, I think that I definitely understated the published beliefs of Sir James Barr.

The electronic theory of Abrams postulated that disease was due to an abnormal vibratory rate of the electrons of the body, and his diagnostic machine was supposed to measure the abnormal vibratory rate, whilst his curative machine was supposed to break down these abnormal vibrations. The theory therefore postulates that both machines are of universal application in disease.

I gather that Sir James Barr is a whole-hearted supporter of Abrams's theory. If he objects to my statement that Abrams's followers believe that all diseases can be treated by one of the boxes, will he mention where either he or the late Dr Abrams has ever published any statement regarding the limitations of the use of the oscilloclast in the treatment of disease? I might mention that I chose the word "treated" instead of "cured" in order to make my statement as non-controversial as possible. I am of course aware that Sir James Barr does not rely solely on the oscilloclast for treatment, in his letter he mentions the use of spinal concussion (spondylotherapy), and in a previous paper<sup>3</sup> he has mentioned other somewhat unusual forms of therapy. For example, he recommended in the treatment of pulmonary tuberculosis the practice devised by Abrams of printing the chest with gamboge and wearing a blouse of printing the chest with gamboge and wearing a blouse or undergarment of yellow silk. Again, in certain cases of epilepsy or migraine he recommended the patient to wear in bed a silk stocking on one leg, the right in the male and the left in the female.

I am genuinely puzzled at Sir James Barr objecting to the suggestion that the oscilloclast can be used for the treatment of all diseases, since this appears to me to be an obvious corollary of the electronic theory of disease.

Since Sir James Barr is the most distinguished electionist in this country, I hope that he will publish a statement regarding the limitations of his belief in Abrams's doctrines. This seems particularly desirable because Dr Reid in his letter suggests that he regards the oscilloclast partly as an adjunct to psychic suggestion, and this seems a very wide departure from the original electronic doctrines.

Sir James Barr actually mentions that the electronic practice attracted a large number of undesirable ecophants and camp followers, and although he believes that these are now discarded, yet it would be convenient if we could know the orthodox electronic faith and thus be enabled to distinguish the regular troops from the camp followers. As a start would Sir James Barr inform the medical profession whether he claims to be able to diagnose the presence or absence of cancer by the examination of a specimen of the handwriting of the patient?—I am, etc.,

A J CROOK

Edinburgh, Oct 17th

### RELATIONS BETWEEN MUNICIPALITY AND VOLUNTARY HOSPITALS

SIR,—At the Annual Meeting of the British Medical Association in Edinburgh this important question was discussed in the Section of Medical Sociology, but unfortunately time did not permit of a full and free discussion of the subject in all its aspects. There are several points which occur to me as worthy of remark.

The scheme is outlined by Mr Eason was fairly put, and, as indicated by Mr Neville Chamberlain, the idea is to place the Poor Law hospitals entirely without the

<sup>1</sup> In Address and Demonstration by Sir James Barr, delivered at the South West of London Post-Graduate Medical Association, Oct 17th, 1924 (Samuel Hill and Sons, Liverpool).

control of the guardians, with this I am in entire agreement as the only true solution, in my opinion, of the proper treatment of patients who require to go either into poorhouse or asylum hospitals.

The Scottish view of the question was attended to by Mr. Renward, chief executive officer of Glasgow parish council and district board of control, whatever that may mean. He began with the frank admission that being a layman, he was not altogether competent to treat the subject from the medical point of view. With this one would entirely concur, as its truth was proved by the policy he had persuaded the Board of Health to sanction—namely, that mental patients could be admitted to Stobhill Hospital and kept there for—if I heard him right—six months instead of six weeks. How the Lunacy Commission can allow this I cannot understand, seeing that for that period the patients have not the protection which the Lunacy Acts give to mental patients. I quite agree with Mr. Renward that the poorhouse hospitals generally are inadequately staffed in comparison with the general infirmaries, and I am afraid Glasgow poorhouse hospitals suffer in this regard, though to a less degree, perhaps, than many of the Poor Law hospitals.

The great defect to my mind in our Poor Law institutions lies more at the door of many of our inspectors of poor. They are the stumbling block officially. Some of the hospitals are in charge of part-time doctors, which is often an advantage rather than a disadvantage, as such doctors have a better chance of obtaining or advising reforms—that is if its councillors are men and women who are out to do their duty to the best of their ability, and not such as those depicted by Dickens.

In my opinion the great and insurmountable defect in the use of Poor Law institutions is that the inmates are really prisoners and are classed as such. The only authority in Scotland that has solved this problem is that of Aberdeen, where the Poor Law hospital has been handed over to the control of the infirmary authorities so that the question of pauper or no pauper never arises. It was a pity that Mr. Renward had nothing to say regarding this solution of the difficulty when, in closing the discussion, he answered various criticisms.

It should be borne in mind that the cost of voluntary hospitals with poorhouse cannot be compared except in the case of combination hospitals where there is a similar basis for comparison.

There is a further objection to parish council institutions in a large city, and that is the possible abuse of their power in converting them into penal places by keeping patients in hospital long after the need for hospital care and treatment is past, several such cases I have met with in my own experience, and I am sure others may remember similar cases.

It is a great pity that a Section which has such possibilities for good cannot be so arranged as to allow so important a question to be discussed in all its bearings. To my mind this subject was not allowed sufficient time for the adequate discussion it merited and in future if the Section of Medical Sociology is to be a success its programme must be more carefully considered in regard to time. Unless this is done the Section will fail in its object and should be done away with—I am, etc.,

Glasgow Oct 16th.

THOMAS RUSSELL

### HOSPITAL POLICY

Sir,—I have been much interested in your leading article on hospital policy (October 1st, p. 601). If the problem is to be tackled successfully a candid statement of facts as they are at present is essential.

I will deal with the conditions as they exist in Liverpool. I am only competent to speak from the physician's point of view. Of the four general hospitals which are associated with the local medical school the smallest contains 100 odd beds, the largest 300 odd beds. The other two hospitals contain over 200 beds.

Let me take the case of a hospital with 200 beds. The majority of these beds are used by surgeons. There will be about 60 or 70 beds at the disposal of the physicians, and there will usually be two full physicians and one or two assistant physicians to take charge of these beds. The

assistant physician, be it remembered, is essentially an independent individual, with his own beds and patients.

It is obvious that a hospital of this size will have great difficulty in adapting itself to modern growth of medicine which makes specialization inevitable. The difficulty is twofold. There are not sufficient beds and material available to make effective special departments. There are only a few nerve cases, a few heart cases, etc., and these are divided among three or four men. Correspondingly, special departments such as pathological biochemical, cardiographic, etc., must remain ineffective because the work can only be carried on on a very small scale.

The other difficulty is still greater. There are really not a sufficient number of trained men to staff the different departments. What frequently happens is this. If a hospital requires, say, a pathologist, it appoints a man to the position who has never had any experience at all on this subject apart from what he gained as a student, and solely by virtue of his appointment he becomes at once an expert in pathology. The same applies more or less to most other departments. A man who, possibly, has been a house-physician for a year and has been acting as a tutor for a few months is appointed to the position of a junior physician. He becomes at once an authority on all branches of internal medicine, ready to act as a consultant and to instruct students. In addition to this, he frequently is a pathologist, a biochemist, takes charge of a nerve clinic, and is quite ready to undertake the work of a cardiographic department. Could medicine be practised on scientific lines by these amateur "experts" at a teaching hospital? The difficulty is that small hospitals entail the multiplication of small, inefficient departments. Things are not so bad with regard to the premier institution in Liverpool.

The progress of medicine is such, however, that it is at present quite impossible for any man to become equally proficient in all its branches. It must not be forgotten that the general physician nowadays usually concentrates all his energies on a special subject, yet he is ready to act as an expert in all branches of internal medicine. If all Liverpool hospitals would amalgamate and thus become one unit, the difficulty would at once disappear. General wards in internal medicine are now no longer compatible with the progress of scientific medicine, but under a scheme of amalgamation it would be quite possible to have, say, 100 beds for nerve cases in one place under the direction of the most experienced man, with the rest of the nerve specialists working under him, all material to be available for all of them, for teaching, and particularly for research. The same applies to other departments. The cost of such a scheme would be really less than at present. It is not, however, very likely that such an arrangement would materialize in the near future in Liverpool.

Sir, I am a believer in the voluntary principle with regard to hospital policy, but if this policy is unable to adapt itself to modern requirements it will have to go—I am, etc.,

Liverpool Oct 16th

I. HARPIS

### ULTRA VIOLET RADIATION AND VARICOSE ULCERS

Sir,—My attention has been called to some comments made by Dr. Weinbre (BRITISH MEDICAL JOURNAL, September 10th, p. 472) on the remarks made in my opening paper on "The uses and limitations of ultra violet radiation in dermatology," at the Annual Meeting of the British Medical Association at Edinburgh (published in the BRITISH MEDICAL JOURNAL, August 13th, p. 255).

In reply to his question, I should certainly include varicose ulcers in the chronic septic type of ulcer benefited by ultra violet light, but it is quite another matter to use it as a routine method for all varicose ulcers. It was exactly this indiscriminate use of actinotherapy for all sorts of conditions to the exclusion of other well tried methods, and the exaggerated statements often made of the results by observers insufficiently experienced to estimate them, that produced the "admittedly pessimistic vein" or my paper referred to by Dr. Weinbre.

I agree with him, however, that there is at present no

standard technique, and unless the method is mentioned, there is no common ground for comparison and discussion—I am, etc.,

London, W 1, Oct 15th

S ERNEST DONE

### THE INJECTION TREATMENT OF VARICOSE VEINS

SIR,—May I point out, with reference to your annotation of September 24th (p 558), that in *La Presse Medicale*, June 2nd, 1926, *xxxx*, No 44, p 689, a full account is given of the histology of veins treated by sclerosing injections.

This method has been in use for the last six years at the Necker Hospital in Paris, where the number of *piquets* given for this purpose is now between 30,000 and 40,000, without any material accident of any kind. I may add that a solution of sodium silicylate is used to the practical exclusion of all other substances and with very great success—I am, etc.,

H BLCKETT-OVERY, M D, F R C S

London, S W 1, Oct 3rd

### OXYGEN IN ACUTE PNEUMONIA

SIR,—When the semi-conscious pneumonic patient is struggling on the borderland his airway may get obstructed by a relaxed tongue as in anaesthesia. This state, which increases anoxaemia, may be counteracted by placing the patient in a semi-propped-up, semi-erect position, which will allow the tongue to fall forwards, or by the attendant holding the jaw forward as in anaesthesia, or possibly by the insertion of an anaesthetic airway. The sound of easier inspiration resulting assures us that we have helped, and that the patient is getting more oxygen.

Is holding the oxygen tube without a funnel immediately in front of the patient's mouth the effective or a futile method of administration? Purgatives involving expenditure of energy are easily overdone in acute pneumonia. Are any needed after the first one if large quantities of water are given?—I am, etc.,

Edington Birmingham, Oct 2nd

W J BURNS SEIKIRK

\*\* The value of oxygen inhalation and the best method of administering it were discussed by Dr J S Haldane, F R S, in the course of a lecture on anoxaemia published in this JOURNAL on July 19th, 1919 (p 65). The best types of oxygen apparatus were described, and one of them was illustrated by a diagram. It can, we believe, still be obtained from Messrs Siebe, Gorman and Co, Limited, 187, Westminster Bridge Road, S E 1. A discussion on the clinical methods of administration and therapeutic uses of oxygen was held in the Section of Therapeutics at the Annual Meeting in Edinburgh, a full report will be published shortly.

### COURTESY CALLS

SIR,—The remarks by "M B, D P H," on this subject in your issue of October 8th (p 664) approximate my own experience closely. I graduated in medicine, after more than four years on active service with the infantry, and bought a practice almost two years ago.

I took an early opportunity to call on neighbouring practitioners. One of my nearest colleagues gave me a very unwelcome reception, together with a rather hopeless impression of prospects of success in the district. Possibly, as my colleague had been at home during the war, my war service did me discredit. Do courtesy calls promote good fellowship as they should?—I am, etc.,

October 8th

B A, M B, Ch B Ed

### ROYAL COLLEGE OF SURGEONS OF ENGLAND MEMBERS AND THE COUNCIL

SIR,—The council of the Royal College of Surgeons of England have just published the result of the poll of the Fellows of the College on the question of the admission of Members to some representation on the council. The voting paper was sent to 1,850 Fellows of these 846 voted "No," and 234 voted "Yes," 770 Fellows did not vote.

Unfortunately—and unfairly, I contend—the council issued with the voting paper a definitely biased and *ex parte* statement of the Members' case. It is remarkable that 770 Fellows did not vote. Also it should be noted that some 600 Fellows are in the metropolitan area—I am, etc.,

London, S W 1, Oct 16th

REYNOLD ROCHF

### DARWIN'S HOUSE

SIR,—In an annotation in your issue of September 10th (p 464) commenting on Mr Buxton Brown's generous offer to buy Darwin's house at Down as a permanent memorial, it is stated that in the year 1842, when Darwin bought the property, it was only accessible by a long coach drive. This is not quite accurate, and in writing of such a master of accurate detail as Charles Darwin one should strive to be exact.

In *More Letters of Charles Darwin*, John Murray, 1903, vol 1, p 31, I find the following letter, which was written to his sister Catherine about two months before he settled at Down.

To Catherine Darwin

Sunday [July 1812]

"You must have been surprised at not having heard sooner about the house. Emma and I only returned yesterday afternoon from sleeping there. I will give you in detail, as my father would like, my opinion on it—Emma's slightly differ. Position. About a quarter of a mile from the small village of Down in Kent—sixteen miles from St Paul's—eight and a half from station (with many trains) which station is only ten from London. This is bad, as the drive from [that is, on account of] the hill is long. I calculate we are two hours going from London Bridge. Village about forty houses with old walnut trees in the middle, where stands an old flint church and the lines meet. Inhabitant, very respectable—infant school—grown up people great museum in all touch their hats as in Wales and sit at their open doors in the evening, no high road leads through the village. The little post house where we slept is a grocer's shop and the landlord is the carpenter—so you may guess the style of the village."

Darwin then goes on to describe the house and garden and surroundings in detail, but the letter is too long for transcription here—I am, etc.,

London, S W Oct 3rd

F MURRAY LATTIS

\*\* Our authority for what we said is the following sentence written by Sir Francis Darwin in *Rustic Southerns* (1917), Chapter X: "It would have been difficult to find a more retired place so near London. In 1842 a coach drive of some twenty miles was the only means of access to Down."

### "THE STRAIGHT ROAD TO A LONG LIFE"

SIR,—Dr Nuthall's interesting article (October 1st, p 600) on Toby Venner's dietetics made me look up a copy (1650 edition), which is also interesting as it belonged to Thomas Lambard, grandson of William the "Perambulator." On the flyleaf under his signature and the date 1659 he has written:

"Phisica est ars bene medendi"

"Est medicinalis Medicorum Regula talis  
Ut dicat da, da, dum dicit Languidus Ah! Ah!"

"The Doctor's practice is to ask for payne  
Even at the time when men cry out for payne"

This is quoted on page 2 of the translator's preface to the reader in Nicholas Culpeper's *Physical Directory* (first edition, 1649). As Lambard and Culpeper were both Kent men and contemporaries it is probable that the book was copied from the other. The price of the book is marked as 2s. As a counterblast I have placed Dance's stipple Alexander Russell, M D, F R S, opposite to this. It has John Locke's lines on Sydenham engraved under it:

"Innocuus phaeide Corpus jubet utere flamma  
Et juxta rapidos temperat Ignis Focor  
Festorist Liches Culteos pessime Venenam  
Abstulit et tritos non Sinit esse Metus"

Both quotations bear somewhat on the "rich quakers" also in the same number. Richard on public a facsimile of Venner's portrait in 1801—I am, etc.,

## Obituary

### MAJOR GENERAL SIR WILLIAM C. MACPHERSON, KCMG CB LL.D.

Colonel Commandant Royal Army Medical Corps

By the death of Major General Sir William Grant Macpherson, which occurred in London on October 15th, the Army Medical Service has suffered the loss of one of its most distinguished Colonel Commandants. As scholar, administrator, linguist, and author he stood out prominently among his colleagues, but his chief contribution to his Service was that 'he timeously prepared against the great day by promoting a proper adjustment between medical military and staff requirements and by initiating the system of voluntary and detachments throughout the country.'\*

From the time he joined the Army in 1883 he devoted himself heart and soul to the Service to which he belonged. Nor did his devotion terminate with his retirement in 1918 at the age of 60.

William Grant Macpherson, third son of the late Rev. William Macpherson, was born in the Manse of Kilmaron Loch, Ross shire, and among the northern hills the moulding of his character began. His early training imbued him with a deep sense of duty, a passion for work, a dom determination to succeed, and a love of thoroughness in all he did. He carried with him through life a delight in the open air and the keen observant eye of the schoolboy. His love of study soon manifested itself, it was the very essence of his being. He was educated at Fettes College, Edinburgh, and to him, one of the most illustrious former pupils of the College, fell the honour of unveiling its war memorial a few years ago. From Fettes he passed to the University of Edinburgh, where, in keeping with Scottish tradition and the trend of ideas at that time, he took up arts specializing in classics. His real ambition, however, was to join the Army and with this end in view he combined arts with medicine graduating with honours in classics in 1879, and M.B. Ch.B. in 1882. Having gained a travelling scholarship he went to Tübingen and Leipzig where he combined the study of medicine with that of German and logic.

To the shaping of his career he brought many gifts, natural and acquired. The driving force behind him was his inherent desire for knowledge and many will remember the quick notes he made in his little black diaries—books that are still preserved. He was gifted with the art of expressing himself clearly and concisely, and his ready pen and ability to sketch helped him on more than one

occasion when a difficult problem or position required elucidation. To these must be added a natural aptitude for learning foreign languages, which not only stood him in good stead throughout his career, but was indirectly of great benefit to the Medical Service itself, as he became an enthusiastic research scholar into the military medical systems of Continental armies, and was thus able to formulate the principles and regulations that guided the Medical Service safely through the great war.

His military career took him to all parts of the world, and wherever he went he acquired the language in order to understand better the problems of the country he was in. His first tour of foreign service was in India, this was followed by five years spent at Gibraltar, where, in

addition to his routine duties, he acted as medical officer of health and for a time edited the *Gibraltar Chronicle*. While at Gibraltar he was sent in medical charge of Sir C. Lush Smith's Mission to Fez in 1892 and of Sir A. Nicholson's Mission to Morocco City in 1896. Experiences he delighted to recall. On the completion of this second tour of foreign service he was detailed for duty at the War Office as D.A.D.G., A.M.D.2, and held that appointment from 1890 to 1902. During this term of office he was selected to attend the sixth and seventh congresses of Red Cross Societies at Vienna and at Petrograd respectively. He was secretary of the Central British Red Cross Committee from its foundation until 1902. While he appreciated the work in these important appointments, the desire for more exciting and practical work in the South African war was ever uppermost but this could not be satisfied, and he had to be content with a mission to South Africa on the termination of his appointment at the War Office in 1902. The result of his investigations is embodied in his "Detailed Reports on Sanitary Conditions relating to proposed Cantonments and Encampments for the Troops in South Africa". In 1904 he was appointed

S.M.O. North China Command, and while serving there he had the rare experience of being attached to the Japanese forces in Manchuria for two years during the Russo-Japanese war. His observations were recorded in concise, educative reports which were published later in the "Medical and Sanitary Reports from Officers attached to the Japanese Forces in the Field". For his services to Japan he was awarded the Japanese War Medal, the Order of the Sacred Treasure (3rd Class) and the Meritorious Service Medal of the Japanese Red Cross Society.

On his return home he was appointed to the staff of the Director-General of Military Operations at the War Office, an appointment which perhaps gave him the keenest pleasure in his career and afforded him the greatest scope for his exceptional qualifications. It meant to Macpherson a storehouse of knowledge, periods of research, the friendship

*Yours ever  
W. G. Macpherson*

\* Appreciation by the Dean of the Faculty of Arts of the University of Edinburgh in presenting Sir W. G. Macpherson for the honorary degree of LL.D. July 10th 1919.

of enthusiastic staff officers like General Nicholson, and missions to Panama and Cuba in 1908. To the combatant staff it brought new and forcible ideas on the value of an efficient medical service, and to the Medical Service itself an enhanced reputation among staff officers. In 1910 he was sent as P.M.O. to Malta, where he earned the thanks of the inhabitants by his strenuous efforts for the prevention of disease. The desire to enjoy the companionship of his only son, then soldiering in Quetta, made him readily accept, in the following year, the appointment of A.D.M.S. of the 4th Quetta Division, and the position as lecturer on military medical subjects at the staff college there from 1911 to 1914. His influence for good and his enthusiasm for medical staff tours and exercises became well known, and roused a real desire among all junior medical officers to serve in the Quetta Division so that they might gain some insight into problems about which their knowledge had hitherto been only superficial. When it became known early in 1914 that the then D.M.S. India, Sir Arthur Sloggett, had been appointed Director-General, Army Medical Services, it was no surprise to learn that he had decided to take Macpherson home as his deputy. So much, 1914, found him again in the War Office, this time as D.D.G., A.M.S., a position he held until October of that year.

His service during the great war was continuous, first as Adviser to the Indian Corps, then as D.M.S. of the First Army in France until October, 1915, followed by a period as D.M.S. of the Force in Salonika until March, 1916, when he returned to France as D.D.G.M.S., G.H.Q., 1st Echelon, an appointment he held until June, 1918, when he was obliged to retire, having reached the age limit. While Adviser to the Indian Corps he had actually visited his son, then serving in a Gurkha regiment, when news was brought him a few hours later that he had been killed in action at Festubert. This was the greatest sorrow of his life and one that he never mentioned.

Several features of his administration during the great war are especially noteworthy. His preparations for big operations were carried out to a point of thoroughness in keeping with his character. Coordinated medical opinion prior to an engagement was to him of the highest importance, and he was instrumental in bringing together the representative D.M.S. of armies to discuss the operations. He viewed with dismay the constant wholesale evacuation of slightly wounded and sick casualties to the United Kingdom, and begged the authorities at home to provide sufficient beds in France to meet this need. The shortage of hospital accommodation, which had been greatly felt at the battle of the Somme, became so acute before the advance to the Hindenburg line that he was sent on a special mission to the Adjutant-General at the War Office to explain the position. Before the battle of Cambrai he fought hard to obtain such information from the General Staff as would enable the medical services to make adequate preparations for the heavy casualties expected, and thus avoid a tremendous wastage in man power. In dealing with the medical services in Salonika he found that a complete reorganization of medical transport was necessary, because the ordinary motor ambulance wagons and cars were of little or no use for front line work in that country. He early realized the danger of malaria to the force, and put forward a most comprehensive scheme for its prevention.

For his services he received many honours and distinctions. Prior to the great war, in addition to his Japanese decorations, he was made a Knight of Grace of the Order of St. John of Jerusalem in 1901, was awarded the C.M.G. in 1902, and was appointed Honorary Physician to the King in 1912. During the war he was mentioned nine times in dispatches, was made a C.B. (Military), a Commander of the Legion of Honour and Crown of Italy (3rd Class) and a K.C.M.G., and was awarded, in 1922, the Distinguished Service Medal of the United States of America. In July, 1919, he received from the University of Edinburgh the honorary degree of LL.D., in honour that appealed to all the sentiment in Macpherson because it half-marked the erudite tendency he had steadfastly developed from his student days, and was received amidst

warm-hearted and friendly fellow students who had likewise won fame and honour.

The years that followed his retirement were devoted to the many public and private interests that filled his life. He was editor-in-chief of the official *Medical History of the War*, compiling, with the help of collaborators, eleven volumes in the short space of four years. He had been a member of the British Medical Association for many years, was the representative of the R.A.M.C. on the Council from 1921 to 1926 and a member of the Naval and Military Committee from 1921 to 1927. He was a member of the Committee on the Expansion of the Army Medical Service in case of National Emergency from 1921 to 1923, of the Committee on the Royal Commission on the Superior Civil Services in India, 1924-26, and chairman of the Special Committee on Tests for Drunkenness, 1926-27. On numerous occasions he represented His Majesty's Government at the Convention of Red Cross Societies at Geneva. He reviewed many books, and was a frequent contributor to works of reference and journals. In particular, we would wish to acknowledge here the readiness with which his wide knowledge, command of languages, and skilled pen were put at the disposal of the *British Medical Journal*.

But what of the man himself? His lifelong principles were duty first and sham or make-believe nowhere. Few men had a kinder or gentler disposition than Macpherson, and, like the true Scot that he was, he had behind a courteous manner a shy reserve and an extraordinarily diffident and sensitive nature. Though he had his disappointments they did not sour him or rob him of his zest for and appreciation of life. In his entertainment of friends at the Savile Club, the Junior United Services Club, at a restaurant, or at home, he was the genial host, ever ready with merry jest and light-hearted conversation to make his artistic dinner a success. In the realm of sport he was no amateur. He was champion boxer and one of the best gymnasts of his year at Edinburgh University. At Gibraltar he raced, hunted, and played polo, while at Quetta his racing matches with the present Adjutant-General, Sir Walter Brathwaite, one of his greatest friends, brought him his most valued trophy—a cup. At golf there was no keener competitor in the Generals' Competition at the Army Golf Meeting or in the British Medical Association golf tournament than Sir William Macpherson, and no one enjoyed more than he the matches played during his annual golfing holidays at Gulluno with Sir Harold Stiles, Professor Leith, and Sir Oliver Lodge. His pride and pleasure were unbounded when his Corps won the Army Championship Cup at St. Andrews in 1926, and to the golfing members of the R.A.M.C. his enthusiasm and joy of life have brought esprit de corps and delight in comradeship. If the last two months of his life were tragic, he bore them without complaint, and to the very end he was the gallant, great-hearted officer who well deserved the name of "Tiger Mae" for his courage, energy, strength, and tenacity of purpose.

He married first Miss E. A. Clunns, daughter of Mr. J. Clunns of New Orleans, she died in 1907. In 1910 he married Geraldine, youngest daughter of General Sir John Dorian, K.C.B., of Ely House, Wexford, and to her and his other relatives we extend our whole-hearted sympathies.

We are indebted to Sir ARTHUR BOYD, Bt, K.C.B., who was Advising Consulting Surgeon at G.H.Q., France, when Macpherson was D.D.G. there, for the following tribute.

I am glad to have the opportunity afforded me by the *British Medical Journal* of alluding to the work done in the war by Sir William Macpherson. He was probably one of the best known men of the Army Medical Service and there must be very many who served in France or in Salonika who remember him and his work. At the beginning of the war he was Deputy Director General in London, but in November of 1914 he came out to France and acted as medical adviser to the Indian contingent, and for a short time. But it was on the formation of the First Army early in 1915 that he had the opportunity of administering a medical service himself. He served D.M.S. First Army during the fighting in March at Neu-Chapelle, and in the May attack at Festubert. Later

the First Army made the attack at Loos, and shortly after this Macpherson was promoted to be DMS in charge of medical affairs Salonika. Of his work in Salonika I cannot speak from any personal experience, but after remaining there for about six months he returned to France to take up the appointment of DDG under Sir Arthur Sloggett in the place of General O'Donnell, who had been appointed Director General in India.

It was while he was attached to the First Army that he first became closely associated with the civilian members of the medical profession who by this time were serving at the front in considerable numbers, and it was in association with the Consulting Surgeon of the First Army (Sir Cuthbert Wallace) that the first steps were taken in that army to improve the opportunities for operative work at the front and it was at the battle of Loos arrangements were made for the first time for an advanced operating centre in support of the casualty clearing stations. It was in the winter of 1914-15 that "trench feet" first came into prominence as a very disquieting source of invaliding and thousands of men in the British Expeditionary Force were incapacitated for service for many months. Macpherson was one of the first to take most energetic measures to prevent this drain upon the army, and I think that the success which attended his efforts was always a source of much gratification to himself.

It was however, after his return to France as Deputy Director-General in 1916 that he became so well known to all medical officers on the British front, and it is pleasant to recall in what a friendly way everything worked at advanced GHQ. It will be of interest to many readers to recall the GHQ staff at that time. Sir Arthur Sloggett was DG, Macpherson was DDG, and the chief staff officers were Majors Buckley, Martin, Morgan, and Black. It was with this staff that I was associated as 'Advising Consulting Surgeon,' and nothing could have been more smooth than the working of the office. Macpherson was the pivot on which most arrangements turned, the general direction was under Sir Arthur Sloggett but Macpherson acted in a position comparable with that of a chief of the staff to his general and it was largely through him that final orders were drafted and that the commands of the Director General were translated into action. It was about the time when he was appointed DDG that special efforts were being made to develop the surgery of the front and before he returned from Salonika steps had already been taken to keep the casualty clearing stations as near to the front as possible and also to add to their staffs operating surgeons of experience and nurses, and to increase their equipment in view of the coming battle of the Somme. The result was that in 1916 a very large percentage of all the wounded were operated upon at the front, and from that time onwards constant improvements were being made in arrangements for the early treatment of wounded men. In all the improvements Macpherson was one of the chief actors, and it was during the battle of the Somme that the system of reinforcement by "surgical teams"—which was such a success—was initiated at the casualty clearing stations. It must also be remembered that not only were the casualty clearing stations at that time much better equipped, but that, as the war went on, the surgical work of the field ambulances also was greatly improved and arrangements were made for the splinting of fractured limbs as soon as possible after the men were wounded. In all these improvements Macpherson bore a leading part and it was largely owing to his example and that of his colleagues at GHQ that the liaison between the RAMC and the civilian surgeons became so friendly and smooth.

But there was another matter in which Macpherson assisted very materially the easy working at the front of the Army Medical Department, and that was in maintaining close and friendly relations with the combatant command. He was very frequently the confidant of army commanders or of GHQ itself, and was thus often enabled to make those arrangements before a battle which allowed casualties to be anticipated and their treatment prepared for. He was all the more useful in this respect because as far as Army Regulations were concerned he might have been described as a walking dictionary, and

although he was sometimes accused of paying too much attention to red tape there is no doubt that he never allowed any such thing to interfere with the efficient treatment of the wounded or sick soldier, whose interests were always in his mind. I remember very well how he pointed out to a civilian medical officer during a battle that in the interests of the wounded man it was most necessary that the details of his wound and the date on which he was wounded should be carefully noted—and this for the sake of the man himself who might possibly have some difficulty in securing a wound pension if his name did not appear among the returns of the wounded.

He was a good disciplinarian but never a harsh one while he was always good tempered, very accessible and open to argument. He was fortunately blessed with a good constitution and robust health, and never appeared to be overtired, however long the day might be. It was a great disappointment to him when the time came for Sloggett and himself to retire from active service just before the termination of the war, but his work was not yet done for after serving as DMS in the Southern Command in England he was selected to act as editor-in-chief of the official *Medical History of the War*, and it is not too much to say that it was mainly owing to his energy, ability, and literary accomplishments, that the medical history was completed within three years, and that owing to his guidance it attained the very high reputation which it holds. It is indeed noticeable that this medical history was completed before similar histories of other combatant nations had been well begun. Macpherson had a very full life and earned distinction in many capacities in the Army Medical Corps, but it is his work at the front during the great war, and his further service as an historian after the war was ended, that will make his name go down to posterity. He will be deeply regretted by his many friends.

At the funeral service in Holy Trinity Church, Brompton, on Wednesday, October 19th the Council of the British Medical Association was represented by Sir Richard Luce, M.P., the Naval and Military Committee by Major General Sir Alfred Blenhusop, the headquarters staff of the Association by Dr. C. Courtenay Lord (Assistant Medical Secretary) and the Journal by Dr. N. G. Horner (Assistant Editor). A memorial service will be held in the chapel of Queen Alexandra's Military Hospital, Millbank, on Tuesday next at noon.

[The photograph reproduced is by Messrs Elliott and Fry, London.]

#### SIR JOHN O'CONOR, KBE, MD

Senior Medical Officer British Hospital Buenos Aires. The death of Sir John O'Connor senior medical officer of the British Hospital, Buenos Aires, is announced by the Ixehungo Telegraph Company. He was the son of Mr. Abraham O'Connor of Carrick-on-Shannon, and was born on December 21st 1863. He received his medical education at Trinity College, Dublin where he graduated MB in 1886, and MD and BCh in 1890. After holding the office of house-surgeon at the Royal Portsmouth Hospital from 1887 to 1889 he went out in 1890 to Buenos Aires to be resident medical officer at the British Hospital there, an institution maintained by the British community, but admitting patients of all nationalities, four years later he became senior medical officer. He established a great reputation as a surgeon in the Argentine and his name became well known in this country owing to his numerous contributions, always highly practical, published in this and other medical journals. Though he made his home in Argentina, he remained ardently attached to the fortunes of the British Empire, and during the war was chairman of the British Patriotic Administrative Committee and of the local Military Commission in Argentina. In 1920 he received the honour of KBE in recognition of this work.

We are indebted to Dr. BRUNO POTTER who was well acquainted with Sir John O'Connor and visited him at Buenos Aires only last spring for the following tribute to his memory.

By the death of Sir John O'Connor at the comparatively early age of 63, the city of Buenos Aires loses one of the

most prominent members of its British community. His great work was done at the British Hospital. He had long been the life and soul of this institution, and when I visited the wards with him only in May this year his interest, enthusiasm, and operative ability showed not the least sign of relaxation or slackening. His experience must have been immense and unique. There was always open to him a great field of labour, for to this hospital the accident cases of the Buenos Aires Great Southern Railway, among others, were brought. He lived in a flat overlooking the splendid Avenida de Mayo in the centre of the city, and to visitors there he delighted to show specimens of his wonderful colour photography, this was a great hobby with him, and his results were remarkable. The photographs were mostly taken at his country seat in the lake district, named by the Indians Nahuel Huapi, in the province of Rio Negro, some seven hundred miles to the south-west of Buenos Aires. This beautiful place is in the foothills of the Andes, at the mouth of the pass through which the Chileans would, if unhappily they undertook such an enterprise, descend to attack the Argentines. Here he would give himself up to hospitality, and revel in it during the summer months of December and January, escaping the heat of Buenos Aires. In Buenos Aires he entertained laugh and merrily at the Jockey Club, where he was much more at home than at the English or the Strangers' Club. He mixed freely and easily with the Argentines, and had none of the aloofness which somewhat handicaps the British community. He knew more than any other foreigner the mind of the Argentine, he could speak the language fluently, and mingled freely with them. He would often refer with pride to the place the British occupied in the estimation of the Argentines. Indeed, he would frequently reiterate that the British were easily first in the regard and affection of Argentines, and the only foreigners who really counted. He was a typical Irishman—he was witty, outspoken, a good raconteur, and impatient of contradiction. His position in his adopted country suited him well, for he loved to lead rather than to follow. His war work was worthy of one who held the highest ideals of the British Empire. I well remember a striking cartoon O'Conor drew to impress on each man his value in the structure and making of the arm. He had two sons, of whom one, a promising officer in whom he had taken the greatest pride, died in the war. Sir John O'Conor was possessed of a vigorous and striking personality. He was a great and versatile surgeon, an Imperialist contributing as much as any man to the prestige of the British in Argentina. Above all, he was possessed of a wonderful charm and kindness, which have endeared him to a vast circle of friends, both British and Argentine.

Dr J G BLACKMAN of Portsmouth, who knew Sir John O'Conor during his time at Portsmouth, writes of him as follows:

John O'Conor was full of enthusiasm for the new era then dawning upon medicine and surgery. His ardent zeal was so contagious that to be associated with him was a post-graduate education. As a surgeon he was at once daring and cautious, yet very original. His many communications to the *Journal* show how generously he strove to disseminate his ripe experiences. His comparatively early death is a heavy blow to the British community of Buenos Aires, as well as to the profession he so richly adorned.

Dr WILLIAM CAMERON MACAULAY, who died in the Middlesex Hospital on September 1st, was born in 1868, and owing to straitened family circumstances had to begin earning his livelihood by teaching at the age of 17. In 1895 he obtained the degree B A Lond with honours in English, and remained in the teaching profession until 1898, being an assistant master at the Westminster City School and tutor in early and medieval English in the University of London. He entered the Middlesex Hospital as first entrance scholar in 1898, when he was 30 years old, and secured almost every available scholarship and prize, in one year, 1904, he was awarded the John Murray Gold Medal and Scholarship, the second Broderip Scholarship, the Governor's Prize, the Leopold Hudson Prize, and

the Hetley Clinical Prize. In 1903 he graduated M B Lond with first-class honours in gynaecology, and second-class honours in forensic medicine, and obtained the diplomas M R C S, L R C P. During his medical education he found time to continue teaching in English, and for several years he held the post of demonstrator of chemistry in the Middlesex Hospital medical school. He held a resident obstetric appointment at the Middlesex Hospital for a year and then commenced practice at Brixton, where he worked resolutely until within a month of his death, save for the entire period of the war, during which he was serving abroad with the 2/5th Field Ambulance. He was an ardent Territorial and was second in command of this ambulance from its formation to its disbandment. He saw active service in France, Salonika, Macedonia, Egypt, Palestine, and Syria, and was mentioned in a dispatch by General Allenby for gallant and distinguished services in the field. Other appointments held by him were those of medical referee to the Ministry of Pensions, and to the Commonwealth of Australia migration scheme. He was a member of the British Medical Association. He died in his old hospital tended by old friends and classfellows, and will be long remembered as a brave man, who faced with the quiet fortitude and courage which befitted a soldier the desperate operations for the malady from which he was suffering. He is survived by a widow and one son, Dr H M Cameron Macaulay, who is deputy county medical officer of health for Middlesex. Mr Victor Bonner writes: I should like to pay a tribute to the late Dr William Cameron Macaulay, whose premature death is a real loss to the profession. He entered his calling late, so that though a student under me, he was considerably older than the rest of his classmates. He was a very brilliant man, and possessed ability which would have fitted him for any position however high. He greatly distinguished himself in all his examinations, and, but for an oversight in his paper, would have obtained the gold medal in obstetrics at the London University. As too often happens to men of the greatest promise, circumstances compelled him to take up a line of work where his great gifts were hidden from the recognition of the general public. That he did splendid though unostentatious work, I can vouch for, and his noble and steadfast character enabled him to meet the tragic fate that befell him with extraordinary courage and fortitude.

We regret to record the death of Dr ROBERT CORRI, on September 25th, at the age of 57, after a short illness. He received his medical education at St Mary's Hospital, where he graduated M B Lond in 1894, and obtained the diplomas M R C S, L R C P. He held the appointments of house-surgeon and obstetric officer to St Mary's Hospital, was resident medical officer at the Ipswich General Hospital, and during the Boer war he acted as civil surgeon. In 1902 he settled in Greenwich, where he carried on practice for the past twenty-five years, and was physician to out-patients at the Miller General Hospital. He took a keen interest in Church activities, and had been church warden at the parish church for many years. At the outbreak of the late war he was called up as a Territorial officer, R A M C, and served in France and Salonika throughout its duration, retiring with the rank of lieutenant-colonel. He was a lecturer for the St John Ambulance Association, and held local clinic appointments under the London County Council. He was a member of the executive committee of the Greenwich and Deptford Division from 1923 to 1926, and was chairman of the Division in 1926-27. His death will be keenly felt throughout the district, where his medical skill and kindly disposition had made him greatly beloved. He leaves a widow and two daughters.

Dr ALFRED JAMES MEYRICK PAGET, who died on September 15th, after many months of failing health, was the third son of Sir George Edward Paget, K C B, formerly Regius Professor of Physic in the University of Cambridge. He was born at Cambridge in 1869, and entered as *Commoner*, was born at Cambridge for the merchant service, but after a year's work was disabled by a severe accident. His year's work then led him to try ranching as a premium

student in Canada, but finding this unsatisfactory he returned at the age of 19 with a desire to enter the medical profession. He obtained the M.B. degree at Edinburgh in 1895 and proceeded M.D. in 1898. His health proving unequal to the strain of general practice, he took service in the following year under the Foreign Office and became a medical officer for the Uganda Protectorate. He got no further than Nandi, where he lay for two months dangerously ill with malaria. He was invalided and then transferred to Kenya, where he spent four years of pioneer work in an unsettled country. From Kenya he went to Somaliland as senior medical officer, and remained there till 1916 through the troubled years of the "Mad Mullah's" activities. He received the Somaliland medal for services during military operations especially for attending and rescuing Colonel Summers when wounded. His administrative work was highly praised and he did much towards starting hospitals and training native attendants. In 1916 he was invalided, and shortly afterwards joined the R.A.M.C. as a temporary lieutenant, he worked in the Lord Derby Hospital, Warrington, and afterwards at Ripon. From 1918 to 1925 he took temporary duty as a neurological expert, chiefly on pensions boards in London. In May of this year his health finally broke down. He leaves three sons, of whom Dr M. A. Paget is a member of the medical profession.

Dr THOMAS O'KELLY of Chipping Norton, who died on September 25th, at the age of 70, received his medical education in Dublin and Queen's College, Galway. He graduated M.D. of the Queen's University of Ireland in 1879, and obtained the diplomas L.R.C.S. Ed. and L.M. in 1883. He was medical officer and public vaccinator in the Chipping Norton Union, and in addition carried on a large country practice. For many years Dr O'Kelly took a prominent part in the work of the Oxford Division of the British Medical Association. He was a member of the Oxford and District Branch Council from 1892 to 1894, and of the Oxford and Reading Branch Council from 1913 to 1922. He was also chairman of the Oxford Division in 1914, and vice-chairman of this Division from 1915 to 1921. Dr William Collier who was President of the Association when it met at Oxford in 1904, writes: "The late Dr O'Kelly joined the Oxford Branch of the British Medical Association soon after its institution in 1885, and proved himself one of its most enthusiastic supporters, he very rarely missed a meeting of the Branch and took an active share in the discussions. No general practitioner ever went to greater trouble to keep up with advances of medicine, as year by year he spent a portion of his holiday visiting the hospitals in London and learning what he could. Needless to say he built up a large and widespread practice in the neighbourhood of Chipping Norton, and was much esteemed and respected by his neighbours, both rich and poor. He gave freely of his best to all. A somewhat long and painful illness was borne with great courage and cheerfulness, and his loss to the neighbourhood is very great."

## Universities and Colleges

### UNIVERSITY OF CAMBRIDGE

At a congregation held on October 15th the following medical degrees were conferred:

M.D.—J. C. Harris \* L. P. Lockhart  
M.B.—B. C. H. J. Burrows \* H. R. Hafield G. P. Chandler M. S.  
Dewhurst  
M.B.—A. C. Copley

\* By proxy

The following candidates have been approved at the examination indicated:

D.P.H. and Hy.—Part II. L. A. P. Anderson H. M. Ayres A. Gilbert  
H. M. O. Mann M. H. M. L. M. L. N. Segal G. Shehata H. Singh  
Mary A. McI. Steven on H. C. Wilkinson

### UNIVERSITY OF LONDON

#### UNIVERSITY COLLEGE

Three lectures on the history of medicine will be given at University College Hospital Medical School by Dr Charles Singer on syphilis (November 7th), influenza (November 14th) typhoid

fever (November 21st). The lectures which will be given at 4.15 p.m. on each day, will be illustrated by lantern slides and are open to all medical students of the University of London.

### UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

The annual dinner of past and present students of University College Hospital was held at the Hotel Cecil on October 14th. Sir George H. Macer presided over a large gathering. In the course of his report on the past year the dean Dr A. M. H. (Craw) mentioned that the centenary of the Medical Faculty of University College fell in 1923. With its new obstetric and mental hospitals University College Hospital now possessed 500 beds and in the matter of buildings and equipment was second to no hospital in London. Among the investigations carried out in the Medical School during the past year he mentioned the synthesis of thyroxine by Dr Harrington, a notable achievement in biochemistry. In conclusion, he referred to the severe illness the hospital had recently sustained in the deaths of its chairman and vice chairman Sir Ernest Hatch and Lord Ormonde Browne.

### VICTORIA UNIVERSITY OF MANCHESTER

The Lancashire County Council has increased its annual grant to the University from £4,000 to £5,000 in addition to the supplementary grant made by them for extramural work. The Cheshire County Council has renewed its annual grant of £10.0.

Dr R. B. Wald who has recently retired from the Leech Chair of Materia Medica and Therapeutics has presented £250 for the endowment of a prize in pharmacology.

Professor J. S. B. Stopford has been appointed the representative of the University on the General Medical Council.

The following appointments have been made: Assistant Lecturer in M.R.C.S. demonstration in I.Sc. M.B. Ch.B. Manchester demonstrator in pathology Mr H. L. Sheehan M.B. Ch.B. Manchester

### UNIVERSITY OF GLASGOW

The following degrees were conferred on October 17th:

D.Sc.—John Glasier M.D.  
M.D.—Aim M. Fleming George Macdonald A.M. A. Scott.  
With honours

The degrees of M.B. Ch.B. were also conferred upon the successful candidates whose names were published in our issue of October 8th (p. 666).

The Branton memorial prize awarded to the most distinguished graduate in medicine for 1927 has been gained by W. A. Mackay.

The West of Scotland B.A.M.C. memorial prize for the candidate with the highest aggregate marks in medicine surgery and midwifery in the final M.B. Ch.B. examination held during 1927 has been awarded to Margaret W. Thomas.

### UNIVERSITY OF WALES

The following candidates have been approved at the examination indicated:

D.P.H.—Part I. C. J. Donelan Nancy K. Gibbs Dyls Jones Part II.  
C. W. Anderson J. D. A. Chapman C. J. Donelan Nancy K. Gibbs  
Dyls Jones E. M. Jones

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

A general Council meeting was held on October 13th when the President, Sir Berkeley Moynihan was in the chair.

#### Annual Report

The annual report of the Council was approved and will be placed before the Fellows and Members at the annual meeting on Thursday, November 17th.

#### Direct Representation of Members on the Council

The Committee on the Annual Report of the Council reported that it had examined the answers received in reply to the circular addressed by the Council to the Fellows with the object of eliciting their opinion regarding the direct representation of Members of the College upon the Council. Circulars were sent to 18.0 Fellows and 1050 replies were received. The question asked was:

In your opinion is it desirable that Members of the College should have direct representation upon the Council? 846 Fellows voted No and 234 (including 6 conditional answers) voted Yes, majority against 612.

#### Lectures

Sir H. J. Waring was appointed to deliver the next Huxterian Oration. The Brantley Lecture will be delivered by Sir Anthony Wallace on November 10th at 5 p.m. on Laryngeal prostatic a review. The Thomas Vicary Lecture will be delivered by Dr George Parker on November 3rd at 5 p.m. on The early development of hospital.

#### Bicentenary of John Hunter

It was decided to celebrate the bicentenary of the birth of John Hunter on February 14th 1923.

#### Honorary Curator

Mr C. J. S. Thompson, formerly curator of the Wellcome Historical Medical Museum was asked to act as honorary curator

of the historical section of the museum (including surgical instruments and appliances) in succession to the late Mr. Alban Dornan, on the ensuing year.

#### Gilbert Blane Gold Medal

The Sir Gilbert Blane Gold Medal has been awarded to Surgeon Lieut. Commander Allan Watt McRorie, M.B., R.N. Promotion Examination, 1927.

#### The Late Mr. Thelwall Thomas

A vote of condolence was passed on the death of Mr. William Thelwall Thomas, M.B.E. Member of the Council. The vacancy in the Council thus occasioned will be filled up at the election of members of the Council in July, 1928.

#### Advancement of Gynaecology and Obstetrics in New Zealand

Leave of absence was granted to Mr. Victor Bonney to assist in the inauguration of a new society in New Zealand for the advancement of gynaecology and obstetrics. Mr. Bonney was asked to convey the best wishes of the Council of the College to the Medical Association of New Zealand for their continued prosperity and for the success of the new section to be formed.

#### CONJOINT BOARD IN SCOTLAND

Five following candidates have been admitted Diplomates in Public Health:

H. Subramanyam, W. B. Moore, A. E. W. McLachlan, J. O. Hamilton, Joanne Kean, C. K. Robertson, J. Douglas, A. McLarnon, A. Gairdner.

Eleanor B. Bone has passed Part I of the D.P.H. examination.

### The Services.

Surgeon Commander H. E. Y. White, C.V.O., O.B.E., has been appointed to H.M. Yacht *Victoria and Albert*. He entered the service in July, 1913, and after serving throughout the war was appointed to H.M.S. *Rivern* in 1919, in which ship he did duty during the Prince of Wales's world tour. He was for two years in charge of the sick quarters at the Royal Naval College, Dartmouth. He again attended upon the Prince of Wales during his South African tour in 1925 in H.M.S. *Repulse*. After serving as principal medical officer of H.M.S. *Queen Elizabeth* he was appointed to H.M.S. *Rivern* in which the Duke and Duchess of York made their recent world tour.

#### DEATHS IN THE SERVICES

Lieut. Colonel Frederick William Wright, D.S.O., Bengal Medical Service (ret.), died at Bournemouth on September 9th aged 76. He was born on December 7th, 1850, the son of Robert John Wright, land agent, Thorpe, Norfolk, and educated at Edinburgh, where he graduated as M.B. and Ch.B. in 1872. Entering the I.M.S. as surgeon on July 1st, 1873, he became surgeon lieutenant-colonel after twenty years' service, and retired on December 7th, 1905. His entire service was passed in military employ. He served in the Afghan war of 1878-80, in the actions at Jagdallah and Chihil-dakhteran, in the march under General Roberts from Kabul to Kandahar, in the battle of Kandahar, and in operations against the Afghans, receiving the Afghan medal with a clasp and the special Kabul-Kandahar bronze star and in the Burma campaign in 1886-88, in the operations of the 2nd and 4th Brigades, when he was mentioned in dispatches, in G.G.O. No. 434 of 1887, and received the frontier medal with two clasps, and the D.S.O. from July 1st, 1887, China 1900, medal and North West Frontier of India, Waziristan campaign, 1901-02, medal with clasp. On January 4th, 1919, he was granted a good service pension. In 1914 he married Edith Bella Freeman of Dover.

Major Christopher Martin Ingoldby, R.A.M.C., died at Sekondi, Gold Coast, on June 22nd aged 39. He received his medical education at the London Hospital and took the M.R.C.S. and L.R.C.P. Lond. in 1912. He entered the army as lieutenant on January 26th, 1912, attained the rank of major on January 26th, 1924, and was seconded for service in West Africa on October 8th, 1924. He served throughout the recent great war and was mentioned in dispatches in the *London Gazette* of March 12th, 1918.

Surgeon Captain Michael Joseph Liffan, R.N. (ret.) died in Guernsey on August 13th. He was educated at the Catholic University, Dublin, and graduated B.A., M.B., B.Ch., and B.A.O. in the Royal University of Ireland in 1901. After serving as senior resident medical officer in the Mater Misericordiae Hospital, Dublin, he entered the navy, attaining the rank of surgeon commander on November 21st, 1916, and retiring with an honorary step in rank as surgeon captain, on August 26th, 1926. He served in the recent great war, receiving the medal.

Surgeon Lieut. Commander John Stephen McGrath, R.N., died recently at Ghisnevin, Dublin. He graduated as M.B., Ch.B., and B.A.O. in the National University of Ireland in 1917 and, entering the navy soon afterwards, obtained his rank on May 1st, 1923. He served during the recent great war, receiving the medal.

Lieutenant Anthony Keppel Jackson Finch, R.A.M.C., died at Allahabad on September 5th aged 25. He was born on June 13th, 1902, the only son of Surgeon Rear Admiral Finch, R.N., and educated at St. Mary's taking the M.R.C.S. and L.R.C.P. Lond. in 1925. He took a temporary commission as lieutenant in the R.A.M.C. on October 12th, 1925, and was confirmed in that rank from February 3rd, 1926.

## Medical News.

THE annual dinner of the Royal Society of Medicine will be held on Wednesday, November 16th, at 8 o'clock, at the Hotel Victoria, Northumberland Avenue.

THE annual general meeting of the Medical Students' Annuity and Life Assurance Society, Ltd., will be held at the offices of the company, 300, High Holborn, W.C.1, on Monday, November 14th, at 4 p.m.

DR. H. C. CAVERON, physician and physician in charge of the department of diseases of children, Guy's Hospital, will deliver the Lloyd Roberts Lecture at St. Mary's Hospital, Whitworth Street West Branch, Manchester, at 4.15 p.m., on November 1st. The subject is "The child in general practice: a study both of temperament and of disease."

THE Fellowship of Medicine announces that Mr. Herbert Paterson will deliver a lecture, entitled "Surgical Hints," at the Medical Society, 11, Chandos Street, Cavendish Square, on October 24th, at 5 p.m. On the same day, at 2 p.m., Mr. J. B. Hunter will give a surgical clinical demonstration at the Royal Northern Hospital, and on October 25th there will be a medical clinical demonstration at the same hospital by Dr. Bruce Williamson at 3 p.m. Mr. Cunningham will give an ophthalmic clinical demonstration at the Central London Ophthalmic Hospital on October 27th, at 4 p.m. The lecture and the demonstrations are free to medical practitioners without fee. From October 24th to November 5th there will be a special course in ophthalmology at the Royal Lying-in Hospital every afternoon at 3 p.m. During November there will be the following courses in medicine, surgery, and the specialties at the Hampstead General Hospital, from 4 to 6.30 p.m.: October 31st to November 12th, a similar course at the London Temperance Hospital, November 21st to December 3rd, in medicine, surgery, and gynaecology at the Royal Waterloo Hospital, occupying the afternoons and some mornings, November 14th to December 3rd, an all-day course in diseases of the chest at the Brompton Hospital, from November 7th to November 12th, in neurology at the West End Hospital for Nervous Diseases, November 21st to December 1st, daily at 5 p.m., in proctology at St. Mark's Hospital, from November 28th to December 3rd, an afternoon course in toxicology at St. Peter's Hospital, November 14th to 26th, and a course in venereal diseases at the London Lock Hospital, October 31st to November 26th, occupying the afternoons and some evenings. Copies of syllabuses are obtainable from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

AT the meeting of the West Kent Medical-Chirurgical Society to be held on November 11th, at the Miller General Hospital, Greenwich, Dr. Edward Mapother will read a paper on "Co-operation by the profession in the treatment of mental disorder." The Paterson Oration will be delivered on December 9th by Mr. Victor Bonney on "Puerperal sepsis."

IN view of the retirement of Dr. Joseph Priestley on October 31st from the post of medical officer of health for Lambeth, after thirty-two years' service, the Borough Council at its meeting on October 13th adopted a motion recording its great appreciation of his high professional and organizing ability, combined with indefatigable zeal in promoting the health and welfare of the borough—"services which have placed it in the forefront of the large boroughs with regard to efficiency in sanitation and the lessening of the mortality rates." Invitations have been issued by the Mayor and Mayoress of Lambeth (Dr. and Mrs. R. S. Pearson) to a reception at the Town Hall, Brixton Hill at 4 p.m., on Thursday next, October 27th, when a presentation will be made to Dr. Priestley by his fellow practitioners of Lambeth.

DURING the first thirty-three weeks of 1927 the number of cases of diphtheria in Prussia was 13,632 with 749 deaths, as compared with 12,192 cases with 576 deaths in the corresponding period of 1926.

THE Society of Miniature Rifle Clubs calls attention to the fact that Captain C. Heyate Vernon, the King's prizeman at Bisley last July, has been largely responsible for the inauguration of a miniature rifle club at Bournemouth. Other amateur practitioners interested in this pastime include Dr. F. H. Kelly, who is an active member of the Imperial Brighton and Hove Rifle Club, and Dr. W. T. Bethune, who belongs to the Inverness Club. Dr. P. G. Harvey of Monmouth presided recently over a meeting of the members of the Monmouth and Chepstow Rifle Clubs, which was convened for the purpose of forming a county rifle association for Monmouthshire. It is suggested that similar rifle clubs might well be started at medical schools under the auspices of this society, and that matches might be arranged between them. Information and assistance may be obtained from the secretary of the Society of Miniature Rifle Clubs, 15, Arundel Street, Strand, W.C.2.

THE Bribery and Secret Commissions Prevention League, of which Lord Lamborne is president, is appealing for members and increased funds, on November 4th the Lord Mayor will preside at a meeting at the Mansion House in celebration of the twenty first anniversary of its foundation. Bribery, it is said, is still rampant in this country and more power is desired to counter this disgrace to trade by calling attention to the work of the League and making the law as regards bribery known throughout the land. One of the great successes of the League was known as the canteen case in which seventeen persons were convicted. As a result of the case the whole canteen system was reorganized. The address of the League is 22, Buckingham Gate, S.W. 1.

A MEDICAL tour is being organized by the Société Médicale du Littoral Méditerranéen. It will extend from December 30th, 1927, to January 7th 1928 and will include Hyeres, St. Raphael, Vence, Grasse, Cannes, Nice, Beaulieu, Monaco, Monte Carlo, Mentone. Full particulars can be obtained from the Federation of the Health Resorts of France, 19, Tristram Square, London W.C.1.

THE September issue of the *Africa and East African Medical Journal* contains an article on malaria which is the first of a series of popular accounts of the common diseases of East Africa, with hints on general lines of treatment for those out of reach of immediate medical assistance.

THE fifteenth annual report of the British Dental Hospital illustrates the progress that has been made since its foundation in 1911. Besides the original centre at Camden Road, London, N.W. dental treatment centres are operating at Lewisham Park, Clapham Common, Hammersmith Road and Holborn. Twelve boroughs have maternity and child welfare and tuberculosis dental clinics and there is one minor ailment centre at Lewisham. The attendance of patients at the treatment centres during 1926 shows a considerable increase on the figures of the previous year and many public lectures on oral hygiene are being given.

A SEVERE epidemic of infantile paralysis has recently broken out in Rumania. A large number of cases has also been reported lately in Germany, especially in Saxony.

As the claim of Dr. Dorothy C. Logan to have swum the English Channel was mentioned last week it ought perhaps to be placed on record that she has since withdrawn it explaining that she perpetrated the hoax in order to show how easy it was to deceive the public in this respect.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communication should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1 on receipt of proof.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the *British Medical Association* and the *British Medical Journal* are **MUSLUM 5671 5672 5673** and 5674 (internal exchange four lines).

THE TELEGRAPHIC ADDRESSES are **EDITOR of the British Medical Journal Antology Westcent London**

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements etc.) **Articulate Westcent London**

**MEDICAL SECRETARY** **Mediscera Westcent London**

The address of the Irish Office of the *British Medical Association* is 16 South Frederick Street, Dublin (telegrams **Bacillus Dublin** telephone 4737 Dublin) and of the Scottish Office 6 Drumshugh Gardens, Edinburgh (telegrams **Asociate Edinburgh** telephone 24361 Edinburgh).

## QUERIES AND ANSWERS

### MOTOR CAR ACCIDENTS

MR H. W. BURLEIGH, secretary and general superintendent of the Hospital for Epilepsy and Paralysis (Valde Vale London W.9) asks secretaries of hospitals throughout the country to send him before the end of October statistics as to the number of motor car accidents treated with a view to obtaining the average length of stay of the patients.

### IONIZATION FOR CATARACT

CHM—With each development of electrical treatment vigorous measures have been taken to ascertain what if any effect these means of treatment have upon eye diseases. X-rays and high frequency have been tried and now ionization which might seem more likely to give beneficial effects for it is a means of transferring of drugs from the superficial into the deeper tissues. The use of ionization has been noticed in the *JOURNAL* but its effect is doubtful. It is certainly ineffective when cataract formation has advanced to such a degree that there are actual opacities within the lens. These the treatment cannot affect for they are definite structural alterations. In the early stages of lens disturbance when bubbles are visible on high magnification it has been thought that ionization has been beneficial in some cases. But the benefits have been no more than have been secured by simpler means of subconjunctival injections with fluids that promote vigorous local tissue interchange.

### PAIN IN DISSEMINATED SCLEROSIS

G.P.—I have had a patient with disseminated sclerosis under treatment for some six years. Organic arsenic and courses of typhoid and T.A.B. vaccines (intravenously) seem to have much slowed the progress of the disease. During the present year an unusual and most troublesome symptom has developed. Not long after the right lower extremity has been straightened as in bed intense sciatica pain comes on especially over the outer aspect of thigh. This is at once relieved by sitting on the side of the bed—that is apparently by relaxation of the spastic hamstring. Aspirin, aspirin and phenacetin, atonal, dial, veramon, grimalin, pyramidal, spasticine and many other drugs have been tried without success. Our correspondent asks for suggestions.

### DOGS UNDER CHLOROFORM

ONCHOF—writes. I have been informed by a veterinary practitioner that dogs, showing, failing respiration under chloroform are revived by continuing the chloroform and the immediate application on the back of the tongue of two to three drops of Scheele's solution of prussic acid. Is there any parallel to this in the human being?

### POISONING AND HANGING

DR J. A. PARRY (Hove) asks for information on any of the following points: (1) Date of earliest recorded trial for poisoning in this country. (2) Date of earliest poisoning trial in which medical evidence was given. (3) Date of same in which any analysis of viscera was made. (4) Any other interesting points bearing on above. (5) Date of substitution of drop method of execution in place of strangulation. (6) Is present method of execution by subaerial or subaerial knot?

### INCOME TAX

#### Practice Sold

EX MEDICUS sold his practice in May last and has now received an assessment notice on the basis of the amount of his earnings for the year 1926. Is he liable on that amount?

No. The assessment is in respect of the profits of the practice for the year to April 5th 1926 and should be divided between 'Ex Medicus' and his successor on a time basis. Thus suppose he sold his practice to A as from May 17th 1926 then he is liable on six fifths of £253—say £33—before deduction of allowances and the balance of £255 relates to the period May 17th 1927 to April 5th 1928 and is applicable to his successor for the period to April 5th 1928. We advise our correspondent to write to the inspector of taxes stating the date of sale of the practice and the name of the purchaser and asking for his notice of assessment to be amended and returned to him. The inspector will presumably take the matter up with the successor and 'Ex Medicus' will ultimately have a claim to repayment for 1927-28 in respect of the tax deducted from his dividends etc.

### Car and Locumtenent Expenses

J.D.H. is in partnership and owing to ill health has to provide a locumtenent and will have to sell his share in the firm. In April of this year he incurred the expense of replacing his car. What relief can he obtain for these expenses?

The amount of the firm's assessment for 1927-28 is fixed by the profit for 1926-27 and therefore the expenses referred to will not affect the total tax payable by the firm for 1927-28. It is of course obvious however that they will operate to reduce the assessment for 1928-29 when in all probability J.D.H. will no longer be a partner. It seems to us a matter for adjustment between J.D.H. and his partner. The gross assessment should be divided between them in accordance with the terms of the partnership arrangement for that year. If for 1927-28 J.D.H. incurs a special expense which will operate in favour of the firm in future years there is much to be said for treating at least a part of such expenditure specially—that is as chargeable to his share of the partnership assessment. Admittedly this will mean that his partner will pay tax for 1927-28 on a greater amount than he receives but on the other hand for 1928-29 the position will be that he will benefit by the deduction

of expenses which are not then being incurred, so that, taking the two years together, he should not suffer any hardship on the basis suggested.

#### Car Replacement

"M H" bought a second hand car for £90 in March, 1925, and sold it in June 1926, for £70, buying a new car for £200. What should he claim?

Any claim he now has is for the year 1927-28, and for that and subsequent years he cannot in our opinion, claim "depreciation" on the old car. That car became obsolete—so far as "M H" is concerned—in 1926, he can claim to include as part of his professional expenses for 1926 the sum of £90-£70=£20 as an obsolescence allowance due under Rule 7, Schedule D, Cases I and II. Also he is entitled to claim the usual percentage depreciation allowance on the £200 (15 per cent or 20 per cent) for 1927-28.

#### Production of Accounts

"T A F T" employed an accountant to prepare his figures last year, this year he made his return himself to save the expense but the inspector of taxes asked for a certified copy of his accounts after his return was made. Since then a formal notice of assessment has been received which agrees with the return already made. Should he employ an accountant in such circumstances?

Presumably the accountant looked into the question of expenses carefully last year, and our correspondent, in preparing his figures for the return this year, has followed similar lines to those then laid down. If so it is unlikely that other allowable expenses would now be discovered and our advice would be that "T A F T" should himself make a copy of the detailed statement of receipts and classified expenses, which we assume he prepared for the purpose of his return, certify it to be correct, and forward it to the inspector, explaining that he does not consider that the facts warrant the payment of a professional accountant's fees.

### LETTERS NOTES ETC

#### INSURANCE AGAINST ACCIDENTS TO DEPUTIES

MR L FERRIS SCOTT F.C.A., Financial Secretary and Business Manager, writes: On page 712 of the JOURNAL of October 15th "Sheffield" writes on the question of insurance against accidents to deputies and says, "I intend in future to cut all this trouble out by only engaging a locum tenens who has insured himself against all risks." I am afraid that "Sheffield" is labouring under a misapprehension, or, alternatively, that there is some means of transferring the liability which is unknown to me. I am under the impression that an employer cannot contract out of his responsibilities under the Workmen's Compensation Acts (except in accordance with special provisions laid down in the Act of which mention is made below), and, further, that the maximum benefit under the Acts for fatal injury (where the workman leaves dependants) is £500 and not £300. Subject to possible correction I would set out the position as follows:

(a) He can run the risk himself and in respect of his own estate (which, I believe, would be foolish). (b) He can, by paying a premium, transfer his liability to an insurance company of repute, which will pay on his behalf such amounts as become due and payable under the Workmen's Compensation Acts. (c) A mutual agreement may be entered into between an employer and his workmen for the substitution of a special scheme of compensation, benefit, or insurance for the workmen, in lieu of the compensation provided by the Workmen's Compensation Acts. All such schemes to be effective must be certified by the Registrar of the scheme as well as favourable to the workmen and their dependants as the corresponding benefits of the Workmen's Compensation Act, and unless a majority of the workmen to whom the scheme is applicable are in favour of such scheme. Should the scheme provide for contributions from the workmen, the benefits conferred must be at least equal to those contributions in addition to the benefit to which the workmen would have been entitled under the Acts. The scheme must contain no obligation upon the workmen to join as a condition of their employment, and must permit of voluntary withdrawal. No insurance effected by a workman would relieve an employer of his liability under the Acts.

I cannot too strongly recommend, either of the Association to insure against his liability, or for locum tenens, but in respect of assistants, dispensers, etc., and for domestic servants who come under the provisions of the Workmen's Compensation Acts, it would be the duty and right of the medical profession that they should take out an approved by the Medical Insurance Agency.

#### TREATMENT OF VARICOSE VEINS BY INJECTION

A FATAL issue to the treatment of a case of varicose veins by injections is reported by Dr O A Olson in the JOURNAL of the American Medical Association for August 27th. A woman aged 35 had been wearing elastic stockings for varicose veins in both legs with complete relief when she received injections on two days with salt solution and calomel five days after the second injection she died suddenly and at the necropsy a thrombotic mass was discovered in the right ventricle. Large thrombi were present in a varicose vein in the right leg, a thrombus was

found in the right internal saphenous vein, with a broken end, there was phlebitis of this vein also. The spleen, liver, pancreas, kidneys, brain and other organs appeared normal, the cardiac muscle and valves were healthy. This incident adds point to the concluding sentence of our recent discussion of the procedure (JOURNAL, September 24th, p 558) when reference was made to the possibility of awkward complications ensuing.

#### MENTSTRUAL "TABOO" IN LITERATURE

DR G LOWELL WEBB (Bexhill-on-Sea) writes: If Dr Robert Hutchison will refer to "Jaboo and the Perils of the South" and "Bulder the Beautiful" (vol. 1 of Sir James I. Fraser's *Golden Bough*) he will find numerous references to the origin of this idea. The crude philosophy of primitive man imposed certain taboos on the priest king, god upon whose health and vitality the prosperity of the country depended, and menstrual uncleanness was one of these, which also extended to the king's worshippers. Moses merely formulated a taboo which had been in existence for many thousands of years previously, as had others before him. It extended to the pollution of rivers, wells, and fountains, herds and crops, as well as to many articles of food, but in certain localities the supposed effects of menstrual blood were utilized in a reverse way for destroying the pests which attacked the crops by making women at this period walk among them. Pliny teases the same ideas, even to the drinking of mirrors and the rusting of razors. Three of Sir James I. Fraser's correspondents informed him that it was quite a common belief in recent years in many parts of England that a menstruating woman should not be allowed to assist at the picking of beef or pork, for fear of decomposition.

DR W M FELDMAN (London, W) writes: In reply to Dr Robert Hutchison's inquiry information on the subject will be found in my book (just out) on *The Principles of Antenatal and Postnatal Child Hygiene* (John Bale Sons and Danielsson Ltd). On p 685 occurs the following paragraph:

The Biblical injunction regarding the semi-isolation of a menstruating woman has recently been explained on a scientific basis. It has been found that during her menstrual period her blood contains perspiration and milk contain a toxic material which is harmful to living tissue especially woman will wilt more. The toxin in the milk the nursing during the

The experimental investigation of the subject was carried out by David I. Macht and Dorothy S. Lobin of the Pharmacological Laboratory of the Johns Hopkins University, and fully recorded in a paper entitled "A physio-pharmacological study of menstrual toxin" in the *Journal of Pharmacology and Experimental Therapeutics*, 1924, xxii, pp 413-66. The results were so constant that the authors could without much difficulty diagnose or differentiate between menstrual and normal saliva (or other body fluid) when unknown specimens were submitted to them. The toxin which has been named "menotoin," is found to have some chemical relationship to oxy-cholesterin.

#### TREATMENT OF FACIAL PARALYSIS DUE TO TYPHOID

DR VERA VITCH (Hartshill Orthopaedic Hospital, Stoke on Trent) writes with reference to Mr. Beattie's description of his split in the treatment of facial palsy (JOURNAL, September 17th, p 438). She agrees that relaxation of the paretic or paralyzed muscles is the accepted principle of treatment and that with the addition of mild graduated faradism in the early stages, and reduction of the muscles when they begin to recover function, is probably all that is necessary in the treatment of such cases. She continues: We have had a considerable number of these cases referred to us at the Cripples' Hospital, Stoke on Trent during the past few years, and our difficulty has been the devising of a mouth brace which the patient can wear constantly so that the paretic muscles shall never be stretched. We have eventually produced a splint on the same principle as that of Mr. Beattie, which we find the patient can wear with comfort. This brace consists of silver plated wire of sufficient strength to maintain the facial muscles in the position of relaxation. The face and ear portion is covered with chamois leather, and the mouth portion is covered with the rubber tip of a No. 6 Jaeger's catheter, so that it can be frequently washed. Originally we used ordinary metal wire, but several patients complained of a nasty taste in their mouth. Silver suture wire was then tried which did away with the unpleasant taste, but the cost of this (7s 6d an ounce) was against its everyday use. The silver plated wire is entirely satisfactory and only costs 7d an ounce. For hospital use ordinary rubber tubing is used, with the open end stitched down. Where a more neatly finished splint is required, then the catgut is employed.

#### PREGNANCY AND GYNECOLOGY

DR ZELICK GRIFFIN (London) writes: I was asked to examine a married woman for an insurance company about May. She was then seven months pregnant (primipara) and had been in the arms otherwise she was in good health. To-day—six weeks after her confinement—I again examined her and found no sign of life. I might add that she gave birth to a girl, which may interest Dr D M Macdonald (*British Medical Journal*, October 1st, p 620).

#### VACANCIES

NOTIFICATIONS of offices vacant in various medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 46, 47, 50 and 51 of our advertisement columns and advertisements as to partnerships and locum tenencies at pages 48 and 49.

A short summary of recent posts notified in the advertisement columns appears in the Supplement at page 163.

## ASPECTS AND PROBLEMS OF COMPARATIVE MEDICINE

### FIELD FOR CO-OPERATION BETWEEN SPECIALISTS IN HUMAN AND ANIMAL DISEASES

BY

J. BASIL BLAXTON, M.A., M.P.C.S.

Professor of Animal Pathology, University of Cambridge

In presenting this small and, I fear, quite inadequate contribution for discussion by the Section of Comparative Medicine I feel that I cannot do better than quote the words of the late Sir Clifford Allbutt in another place and upon a similar occasion:

If for years slowly and almost silently our work makes its way we must be content our experience of the world teaches us to be content but happily now and then after long leaning in the darkness we break into light we find ourselves almost suddenly upon a peak our way open and bright before us and our call justified before men. The barriers of convention which ought to be so slender and occasional are of all the most inveterate and impregnable. Of such have been the barriers dividing medical sciences which to its grievous injury have split up medicine into fractions. As physics was divorced from surgery and mind from body so the diseases of animals and plants were separated from those of mankind.

In that last sentence Sir Clifford put the case of what is called comparative medicine in a few words. It has become separated from the mother science medicine. For some reason or other but probably through ignorance of what has gone before, comparative medicine has come to be regarded by many as something in the nature of an innovation—a breaking of new ground, an inoculation of new ideas and perhaps even the initiation of a new branch of the science of medicine. But this is not so. During the past century there has been a steady, sure progress in the study of comparative medicine in all parts of the world but especially in tropical and sub-tropical countries. The reason for this is that animal diseases particularly those caused by protozoal parasites and invisible viruses have been recognized as a serious economic menace, and therefore more or less adequate facilities have been provided for their investigation. The general progress which has been made in comparative medicine appears to have received but little notice, indeed it is not an uncommon experience to find the comparative aspect of the many cases of the mother science medicine regarded as something quite new—in fact almost unique, or at best a more or less comprehensive recital of some of the diseases of the lower animals which may affect man also.

This misconception of the real state of affairs is probably easily explained. The encyclopaedic tradition which had persisted from Aristotle through the Arab and medical schools down to Herbert Spencer has ceased to exist. It is forced upon us in our own day that in a pursuit so many-sided as medicine, whether in its scientific or in its practical aspect we have to submit more and more to that division of labour which has been a condition of advance in all other walks of life. It is now fully recognized that that division of labour which may appear to disintegrate the mother science of medicine really unites it. While pathology, for example which is especially the science of medicine, was winning territory on one side from physiology of which in a sense it is but an aspect and on another was making progress of its own in the post-mortem room and museum of morbid anatomy, and was fusing these gains in the laboratory so as to claim for itself as a special branch of science by virtue of peculiar concepts its due place and provision—provision in the establishment of chairs and of special laboratories for its chemical and biological subdivisions—clinical medicine was illustrating the truth of the experience that teaching and research must go hand in hand, the one reinforcing the other.

Unfortunately, the necessary development of specialism has led to the almost inevitable sequel—water-tightness. The many children grandchildren and great grandchildren of the mother science seem in their self-centred interest to forget that they are but the offspring of the parent. That branch which deals with the comparative aspect of disease has been accused of drifting, farther and farther away from the parent sciences during the past century, but the fault if fault there is is not peculiar to that one branch of medicine. Fortunately the current of thought is not changing and the attitude of splendid isolation is less evident. Any attempt to prescribe a dividing line between the scientific study of the diseases of the lower animals and those of man is inevitably doomed to failure, and this fact is fortunately becoming better realized. Pasteur shed light upon all aspects of medicine but above all upon comparative medicine. The stimulus provided by the master has been directly responsible for the world-wide progress which has been made during the past century. But an attitude of complacency must find no response in the hearts or minds of those who are engaged in contributing to the study of comparative medicine.

A most cursory survey of some of its many problems which have been or are in the process of being investigated cannot fail to create in the minds of those who are responsible for the prosecution of those and similar problems an overwhelming sense of responsibility in relation to the general well-being of men and animals.

The field of comparative pathology perhaps affords one of the best examples of the essential nature of the demand for close co-operation between specialists in the study of human and animal diseases. This does not for one moment suggest that the importance of such co-operation rests with a discussion of those diseases which affect both men and animals, for however important the may be they are relatively few in number in comparison with the diseases which are peculiar to the individual species but which nevertheless, have a general importance in the study of disease processes as a whole. It is true that the fact that a causal organism is common to both man and the lower animals greatly facilitates the work of the histologist, bacteriologist, immunologist, and epidemiologist. Tuberculosis probably affords one of the best examples of this for it is only by the study of the artificially produced disease in experimental animals and in those which require the disease under natural conditions that much of our knowledge has been gained, and it is certain that any advance in the prevention or cure of tuberculosis in man will depend upon observations made in animals. Again recent advance in the investigation of tumours has resulted from work carried out in animals in which experimental tumours can be produced, and others in which a peculiar form of tumour occurs naturally. One cannot fail to be impressed by the possibilities which might result from a systematic study and comparison of the apparently closely related neoplasms which occur in man and in various of the lower animals.

Whatever may be the outcome of the controversy concerning the etiological identity of the variolae of man and the lower animals, the fact remains that the observations of Jenner were of fundamental importance in establishing at least a cross-speciesity in the case of cow-pox and small-pox, and it is equally certain that any progress which may be made in the study of cultural and immune processes will depend upon investigations into the variolae of the lower animals.

Unfortunately, from the experimental point of view, it does not infrequently happen that the causal organism of a disease in man is either non-pathogenic for the lower animals or produces in them lesions which do not resemble the human form of the disease. In such instances it is impossible or at least difficult to study etiological and preventive measures which might be applied to the human subject. But it is sometimes possible to find that a disease peculiar to one animal species has a very definite resemblance to a disease which is peculiar to another species—as, for example distemper in the dog and influenza in man. A comparative study of the two diseases may reveal many common features and knowledge gained from the study of the one may prove to be of value in the study of the other.

Port of a discussion at a joint meeting of the Sections of Comparative Medicine and Bacteriology at the Annual Meeting of the British Medical Association, Edinburgh, 1927. Principal G. C. B. and Dr. J. B. Blaxter.

As a result of investigations into a number of the diseases which are peculiar to certain of the lower animals and which are caused by invisible viruses—for example, rinderpest, foot-and-mouth disease, dog distemper, and others—several methods of inducing immunity to the disease have been devised and it is reasonable to hope that, apart from the benefit which is likely to be conferred upon the animal host, further research may reveal the possibility of applying similar methods to diseases of a like nature which are peculiar to man.

The impetus which was given to the study of the microbial infection of wounds during the war has left its mark upon the bacteriology of several diseases of the lower animals, for while it was previously well known that many of the spore-bearing microbes which were found to play an important part in the pathological complex "gas gangrene" were commonly associated with certain well known and similar diseases in the lower animals, great progress was made in the etiological, cultural, and toxicogenic properties of these organisms as soon as their significance in the military economies of the time was realized. Under normal conditions, however, they are of little importance in pathological conditions in man as compared with the lower animals, and it is certain that, while the further study of these organisms may receive but little attention at the hands of the human pathologist under peace conditions, much further light will be shed upon their relationship to pathological changes in the lower animals, and upon specific toxicogenic variations in members of the same family—as, for example, has been observed in the case of *B. botulinus*.

Quite recently nutritional diseases have occupied a prominent position in comparative medicine. Contributions to the study of various aspects of organic and inorganic deficiencies under experimental conditions have done much to increase our knowledge concerning the probability of certain diseases of animals which are kept under apparently normal conditions being due, in part at least, to a deficiency of one or more of the accessory factors. One of the most important questions which have arisen as a result of purely laboratory experiments is whether, and to what extent, the results obtained with one animal are applicable to the case of other animals and to man. We know from carefully conducted experiments that deprivation of vitamin B will cause paralysis in rats as well as in fowls and in pigeons, that the elimination of vitamin C from the diet of monkeys and guinea-pigs will result in the production of the characteristic haemorrhages and bone lesions of scurvy. Similarly, in rabbits fed with such limitations, while there is an absence of haemorrhages the characteristic pathological changes can be observed in the bony tissues. While rats, on the other hand, are little affected by the absence of vitamin C in their diet, but fail to breed satisfactorily under such conditions.

The absence of vitamin A has been shown to result in ophthalmia (first described by McCollum in rats) in poultry and in infants, in defective calcification of bone in puppies, rats, poultry, and young children. And further, the action of light in correcting a deficiency has also been demonstrated. Thus there is a schedule involving several vitamins and a series of corresponding "deficiency diseases." But there is an even more important issue represented by the widespread disturbances of a non-specific nature which are perhaps produced by vitamin deficiencies—disturbances which have a direct effect upon the severity of other diseases, especially bacterial infections. It is not an uncommon experience, when investigating widespread outbreaks of disease, especially in pigs, to find that the organism which appears to be responsible is one which, under ordinary conditions, is regarded as of little pathogenic significance, yet it appears, for some inexplicable reason, to have developed an exalted virulence. The reaction usually appears to be well balanced and all that could be required, yet slight alterations in the constituents—especially in the direction of increasing the amount of vitamin C—frequently lead to a marked improvement in the general condition of the animals.

Another and equally important aspect of deficiency diseases has been investigated at the Rowatt Research Institute, Aberdeen.

Research into some problems of mineral metabolism has already been productive of information of considerable economic and scientific value. Investigations have shown that natural pastures with a low content of minerals have a low nutritive value for sheep, and that not only is the percentage of progeny from these animals low, but the mortality is often high. These and similar observations are proving of considerable importance, not only in the case of animals in this country, but particularly in some of the colonies. Of no less importance are the experiments which have been carried out to show that artificial ultraviolet irradiation is capable of increasing the absorption and retention of calcium and phosphorus in young pigs. Again, the importance of colostrum in the early life of young animals, apart from its purely medicinal effect, is well known, especially in regard to the temporary protection which it is believed to afford against bacterial invasions. It has hitherto been generally assumed that this protective power is to a large extent due to the high antibody content of the material, but it has been found that the iodine content is also very high, and in view of the claim which has been made that the feeding of potassium iodide to mares is a preventive of joint ill in their progeny, the possibility that iodine may play an important part in the protection of the newborn animal against disease is worthy of serious attention.

Investigations into the physiology of reproduction which have been carried out at the Animal Nutrition Institute at Cambridge have added considerably to our knowledge of these normal processes, and open up a large field for investigation into the abnormal conditions which are so commonly met with in the lower animals and in the human subject.

Marshall's contribution to the study of the conditions governing parturition cannot fail to stimulate further research in this direction, especially since, as he points out, although certain factors are common, the conditions, though generally constant within a particular species, vary widely in different species, and even among closely related forms as well as in individuals.

There are, of course, many other aspects of deficiency diseases which are of great interest from the comparative point of view, there no doubt will be dealt with by others who are to take part in the discussion.

Experimental comparative physiology has not received the attention which it deserves, especially in the case of the lower animals. It has not infrequently happened that an attempt has been made to study the abnormal rather than the normal, often with results which, if capable of any sort of interpretation, have been entirely misleading. There is an enormous scope for research which will lead to a better understanding of many of the normal functions of and processes in the animal body. Such a study should progress with, and not independently of, that of the abnormal.

Another aspect of comparative medicine is that which has been termed tropical veterinary medicine. Here, again, the relationship between the diseases of man and of the lower animals is of the most intimate character. We may take as a fair example of this those which have been grouped under the heading of trypanosomiasis. The classification of the causal parasites is now recognized to be far more difficult than was originally supposed. The morphological and biological characters are in themselves insufficient for this purpose, whereas the mode of development in the fly is of fundamental significance. As a result of more recent work, it has been found to be necessary to recognize different strains of the same species of organism, but the process of evolution of such strains yet remains to be determined, as also do the changes in virulence and in morphology which result from passage. There is also a call for improvement in the methods of diagnosis of infection with the various species of trypanosome. Watson showed the value of the complement fixation test in the diagnosis of dourine, while J. M. Robin in South Africa has confirmed this, and in addition has shown that animals infected with *T. brucei* react to the test even if *T. equiperdum* antigen is employed, while the serum of those affected with *T. congolense* or *T. vivax* does not usually react in the presence of that antigen, but it may do so with the specific antigen. The many

chemotherapeutic problems relating to these diseases which yet remain to be solved can only be satisfactorily carried out in animals, and preferably in those which are naturally the subjects of the disease.

It would not be possible to close even such a sketchy and incomplete contribution as this undoubtedly is without some reference to the vast field of experimental comparative medicine represented by artificially acquired immunity. Since the time of Pasteur it has been recognized that experimentation with animals offers the only satisfactory method of determining the relative merits and demerits of the various methods of inducing a state of specific resistance to disease not only on account of the relatively small size of the subject but because large numbers of animals can be employed for the purpose and, moreover, they can be maintained under natural conditions. Observations upon active immunization of horses against tetanus by means of toxin-antitoxin mixtures rendered a similar procedure possible in soldiers during the great war. Parallel experiments which have since been carried out with the modified toxin of other spore-bearing anaerobes have enabled us to confer an active immunity against a variety of diseases of sheep. The use of bacterial suspensions, consisting of living virulent or avirulent organisms, or of those which have been killed by a variety of means has enabled us to control a number of serious epidemic and enzootic diseases of the lower animal. Experimentation along these lines is constantly progressing and cannot fail to be of economic importance from the agricultural point of view as well as from that of mankind.

For an opening address on the subject of some aspects and problems of comparative medicine I realize that my remarks may be considered too narrow in their scope. But the aspects and the problems are so many, while the range of choice so extensive, that it is impossible in the present circumstances to do more than mention a few and that in a very cursory manner. Those who are to follow me will no doubt make good the deficiencies which are so very obvious in my remarks.

#### DISCUSSION

Dr ANDREW BALFOUR (London) thought that one aspect of comparative medicine which would appeal to all was the essential unity of human and veterinary medicine, one problem well worthy of discussion was how this unity might at least in some degree be realized. This was probably better exemplified in the field of tropical medicine than elsewhere. As comparatively recent examples he cited Pfeiffer's work on rabbit coccidiosis and its relation to human malaria and Theobald Smith's work on the tick in Texas fever, since those days human and veterinary medicine had advanced hand-in-hand in the tropics. He recalled Sir Patrick Manson's announcement about Ross's work twenty-nine years previously his talk was largely about sparrows, crows and mosquitos. After referring to trypanosomiasis, leishmaniasis, virus, ankylostomiasis, rickets and bubonic plague, he passed to the consideration of the experimental method, and the necessity of enlisting the aid of the veterinarian when employing animals in medical research. He maintained that no laboratory engaged in work on tropical medicine was properly and fully equipped unless veterinary medicine was represented, and he mentioned in this connection the system in operation at the London School of Hygiene and Tropical Medicine with special reference to the value of its association with the Zoological Gardens. He regretted the tendency to cleavage in tropical medicine and pleaded for combination under a research roof while routine and clinical work could be carried out in laboratories attached to the respective hospitals. He hoped that the new Research Committee of the Colonial Office would accomplish something in this direction.

Dr W. H. ANDREWS (Ministry of Agriculture) remarked that the problem of the filterable virus was furnished an excellent example of the essential unity of pathology and of medicine on the scientific side although in the practical applications there were fundamental differences. The filterable viruses and the diseases they caused were now

attracting much attention in medical and veterinary circles in both temperate and tropical regions. They constituted the most urgent problem of the present day, and the slow progress in their study suggested that new conceptions and a new technique were needed. Veterinary pathology had already furnished much that was valuable for the human pathologist but more could be expected from research work organized on less restricted lines than in the past. The veterinary pathologist should have the great advantage of working with experimental animals of the species naturally infected by a disease but the advantages had usually been sacrificed to financial considerations. It was known how narrowly specific might be the relations between host and parasite and it should be recognized that among pig and rabbit studies however convenient and valuable (as long as their limitations are realized) could be entirely misleading when applied to animals of other species. Moreover, the reaction to a poisonous substance could also be narrowly specific for example *Melospiza melanocephala* apparently harmless to all other domestic animals, induced a fatal intoxication in hares. Recent work on chronic plant intoxications in animals had great interest for the human pathologist, but much of it was not at all widely known. In connexion with mineral deficiencies the outstanding work of Thelander and Green at Pretoria deserved special mention. They had succeeded in establishing the etiology of the bovine disease "metabolic" but their work had had result far exceeding that of controlling himself, although that disease had formerly caused very heavy losses indeed (see JOURNAL September 24th p. 559). With respect to vitamin deficiencies, it seemed very doubtful whether any of the domestic herbivora under ordinary conditions ever suffered severely from this cause, but specific avitaminoses occurred naturally in pigs and dogs, and probably in fowls also. Dr Andrews felt confident that however important such work might prove later to the human pathologist the study of the diseases of the domestic animal would be best and most successfully pursued for its own sake, although human and veterinary pathologists should naturally co-operate and exchange information as freely as possible.

Mr G. W. DRYDEN M.R.C.V.S. (Mill Hill) stated that the vast fields awaiting investigation and the numerous diseases common to man and the lower animals lent ample support to the suggestion of closer and more intimate co-operation between human and veterinary medicine. The Section of Comparative Medicine of the Royal Society of Medicine was flourishing its membership was still increasing and its meetings continued to be of the greatest interest to both branches of medicine. Nevertheless the facilities already existing for co-operation between the two branches were inadequate for the necessary development of this term work. He stated that, with Dr Laidlaw he had been engaged for the past four years in the investigation of dog distemper. Although this disease was specific for the dog and ferret and did not affect human beings, there were, nevertheless, many phases which closely resembled other conditions in man and it was hoped that the results of this research would tend to the better understanding of certain human ailments. Another disease (John's disease of cattle) which was receiving his attention did not, so far as he knew, possess any analogy in human medicine but it was evident that the results would not be without interest to human bacteriologists and pathologists. It was good to know that diseases of lower animals and their investigation could be of assistance in this way, but he submitted that they were matters for team work in order that a better understanding of the baffling pathological conditions could be obtained.

Mr JAMES McALLAN M.R.C.V.S. (Aberdeen) suggested that the public health aspect of comparative medicine was by no means the least important, and he emphasized the necessity for a very close co-operation between the two professions. In the field of meat inspection while the medical officer of health would always have the last word on the fitness or unfitness of meat for human food it seemed necessary that the veterinary surgeon should co-operate, since he had the better knowledge of animals in health and disease. In Scotland this co-operation had

been fully established. In the production of milk from the hygienic standpoint the veterinary surgeon had a big field, which was further extended by the control of milk-spiced tuberculosis. From personal experience the speaker could emphasize the value of co-operation between the two professions in the investigation of food poisoning outbreaks spread by milk. On two occasions he had been able to trace milk-borne outbreaks of food poisoning to the infection of cows with *Gaciner's bacillus*. It was on such occasions that he appreciated clearly the value which would accrue to medical practitioners from making full use of the veterinary surgeons on the public health staff.

Professor D C MATHESON, FRCVS (Edinburgh) said that for the past fourteen years he had acted as veterinary pathologist to the Scottish Zoological Society. As a matter of routine every herbivorous animal was examined microscopically for anthrax before the necropsy, while in the case of carnivores the possibility of glanders had always to be considered. These animals frequently suffered from "menage pneumonia," and cultures from the lesions on potato often yielded an early growth of *B. coli* with a superficial resemblance to the glanders bacillus. A recent survey of the records showed that among the animals, excluding birds, tuberculosis occurred in 4.7 per cent., in birds the incidence was 7.1 per cent. Among domestic fowls examined in the laboratory for the same period the incidence was 10.3 per cent. Impaction of the intestine by vegetable fibre, twisted by the peristaltic movements into a veritable rope, was not uncommon among the larger cursorial birds such as the ibex. Impaction of some portion of the intestine, usually with vegetable fibre, was responsible for death in 10.1 per cent of the fowls examined during a period of thirteen years. Neoplasms were rare among the animals in the gardens.

Dr J G NASMITH (Edinburgh) emphasized the necessity for investigations into the origin of epidemic and epizootic diseases, and into the periodicity of epidemic diseases that were now controlled and no longer seriously menaced the health of the community. It was also desirable to know why, in the case of "epidemics," the causal organism was able to lie dormant for long, and yet, when a suitable host offered, assert its pathogenic power. He also emphasized the importance of co-operative and co-ordinated investigations by the biologist and the biochemist in association with the pathologist and the clinician. He believed that it would be to the benefit of comparative medicine if the Veterinary College were affiliated to the University, and the Animal Diseases Research Association were similarly linked to the Veterinary College in Edinburgh. Such affiliations he was convinced would lead to co-ordination in research, and the consequent benefit of mankind by the discovery of the fundamentally common conditions which caused human and animal diseases.

Dr F A E CREW (Edinburgh) remarked that so much stress had been laid upon the need for greater co-operation between the medical and the veterinary professions that he could not refrain from asking whether they knew of what and to whom they spoke. Co-operation in research must always be between individuals. He who sought help eagerly found it, if such help was available, in the communion of minds. Those engaged in research were conscious of shortcomings, and the true searcher after knowledge recognized no monopolies. The knowledge of one was available for all. Co-operation was not based on professional organization but on common humility, for no professional organization could override personal antagonism. Far too much was made of the distinction between the medical practitioner and the veterinarian, it was the problem and technique of investigation, and not the material, that really united men. Medicine was too disposed to content itself with study of the causes and the effects of disharmony. They ought to recognize clearly that the control of the future evolution of man and of animals lay in the hands of man himself, and that they must help to decide what man should become and how animals might evolve, setting themselves the task of guiding man and beasts in the lines of their destinies. It was for them to think of the eradication of those hindrances,

and the securing of that degree of material and physical comfort which was a prerequisite of spiritual development. Then great contribution would concern the breeding of man and animals naturally highly resistant and immune to diseases which threatened their existence.

Professor D T GRAY (Liverpool University) believed in the advantage to human medicine of the study of comparative pathology. His own pathological museum contained many specimens of animal disease which he used in teaching medical students.

Mr W A POOL, MRCVS (Edinburgh), stated that there was obviously agreement as to the necessity of greater co-ordination between the two branches of medicine. Investigation of factors concerning animals, both in health and in disease, had in the past been almost limited to consideration of those which were of immediate economic importance or of use in throwing light on problems affecting mankind. As a result they lacked a certain knowledge of many things which should at the present day be well understood. Outstanding examples could be quoted in the field of physiology, such as digestion in ruminants and ungulates, and also in connection with pharmacology, as, for example, the action of certain alkaloids on the autonomic nervous system of equines. This was due to research into animal problems being limited to those of urgency and by methods of applied science, there had not been enough investigation for the sheer desire for knowledge. Prominent examples of problems in which greater co-ordination of the two branches of medicine was necessary were the study of the streptococci of the bovine udder and the effect of nutrition on resistance to disease. The policy adopted in distributing public funds to finance investigations into problems of animal disease tended to foster this policy of attending only to questions of immediate practical importance. Subsidized laboratories were expected to justify their existence in the eyes of the public as they proceeded. This entailed the early and frequent issue of reports, and, to ensure the certainty of having something to report, investigators felt bound to hunt their sphere of action largely to problems which, while being of immediate practical importance, were also likely to produce definite results.

Lieut.-Colonel L D W GRIG (Edinburgh) strongly favoured close co-operation between medical and veterinary pathologists. From his experiences in the last few years several instances of the importance of this combination including the investigation and treatment of rabi and the study of tuberculosis in India. He was convinced that the recent appointment by the Colonial Office of a Medical Research Committee would help materially in co-ordinating research in the two branches overseas.

Dr T W M CAMFORD (London) drew attention to the fact that no one had yet attempted to formulate a definition of "comparative medicine." There was a tendency to regard it as veterinary medicine, or, more frequently, as veterinary diseases in relation to man. He thought that it was neither of these. Defining medicine as the art and sciences of preventing or removing disease, then comparative medicine was the comparison of the art and sciences of medicine as relating to man, the domestic animals, the non-domestic animals, and even plants. Of these, probably the most important was comparative pathology. If physiology were regarded as a study of the normal reactions of an organism to normal stimuli, then pathology was, for the most part, the study of the normal reactions to abnormal stimuli, neoplasms and similar conditions. Of unknown etiology might well prove to be short of reactions to either normal or abnormal stimuli. Comparative pathology, then, would be the comparison of the reactions of various hosts to the same harmful stimuli. Its aim would be to elucidate the fundamental laws underlying the methods by which the body became diseased and by which it fought against disease. This while including both human and veterinary pathology, was co-extensive with neither. It was, moreover, concerned not from bacteriology or parasitology, sciences concerned with causes only, while pathology was concerned with effects.

The speaker then illustrated this concept of comparative pathology by describing the reactions of a variety of hosts to the tubercle bacillus and to the hydatid cyst. Comparative pathology was a natural sequel to comparative physiology, and was a subject as capable of standing by itself in the university curriculum as any of the other divisions of science. If comparative pathology and the other ancillary medical sciences were regarded in this way, then obviously comparative medicine should really be called "medicine" and what was generally regarded as "veterinary medicine" should be rechristened "human medicine." Man was only the most domesticated of the mammals and in these neo-Darwinian days there was no reason why an unqualified name should be given to the purely human sciences while grouping those concerned with the other domestic animals under the cumbersome title of "veterinary medicine." He could not accept the statement that human medicine was the mother of veterinary medicine; she was merely the elder sister who for so many years had acted as foster mother. The true parent was only now being recognized as comparative medicine and it was to her that both the sisters, the elder as well as the younger, must look for the fundamental principles which were necessary before any real understanding of disease was possible.

## TREATMENT OF TOXIC GOITRE

### I.—THE PLACE OF SURGERY IN THE TREATMENT OF TOXIC GOITRE

BY

T. P. DUNHILL, M.C., M.D.

Assistant Director of Surgery, St. Bartholomew's Hospital

I HAVE chosen the term 'toxic goitre' because I believed it would be the wish of this meeting to discuss the treatment of the types of goitre which cause ill health through disordered secretion.

**Clinical Terms.**—There will not be universal agreement on terms. That is because although most goitres fall into well recognized clinical types many minor differences occur. Any two types are linked up by intermediate cases.

Pathologically also many cases fall into definite groups but practically every type of histopathological condition may be found somewhere in a diseased thyroid gland. There is a tendency to multiply types and subdivisions but I have come to feel that the different types are related, I believe pathological evidence is tending to bear this out, and that it will ultimately be found that the differences are only in degree. Take exophthalmic goitre, with which, in its orthodox manifestations, we are familiar. Clinically we recognize a primary and a secondary type of this but we may not be able to define where the primary type ends and the secondary type begins. Histopathologically also we recognize a primary and a secondary type, but some cases which histopathologically are undoubtedly secondary would clinically have been considered primary. There may be great differences between examples of the secondary type, and some of them approach very closely to what we are in the habit of calling toxic adenoma.

As we examine the symptoms we see progressive differences which conform to the differing appearances in the gland. A case of primary Graves's disease has well defined features: an early secondary case is scarcely distinguishable from it. In the late secondary case exophthalmos has become less and may scarcely exist; the nervous phenomena are less obvious, but the cardiac changes are more manifest, auricular fibrillation occurring frequently. Working backwards from the other end of the chain a toxic adenoma is well recognized, but sometimes there is more than one adenoma and, farther still, a gland may be bilaterally symmetrical, the nodules in it scarcely recognizable as adenomata capable of being shelled out (as is a single

adenoma), the whole gland approaching the type of late secondary exophthalmic goitre.

**Etiological Factors.**—What are the etiological factors which cause the differing appearances? Why does the gland of a primary type appear to be a solid cellular organ? and why does the gland of an early secondary type often look like a simple colloid goitre, and a late secondary look like an old fibrotic goitre with some adenomatous masses in it? We presume that a thyroid gland is normal until puberty approaches. We can agree that there is at that time of life a tremendous but quite normal call on the gland, for we believe that the thyroid secretion determines the energy output of every cell in the body. This extra demand is successfully met in the majority of people, but in order to meet it there is some temporary hypertrophy—possibly not enough to be noticed, possibly just noticeable, and, if so, rightly called a physiological hypertrophy. Involution should occur after the demand is successfully met, but if the demand is not successfully met involution does not occur and a colloid goitre remains. These processes occur in meeting a physiological stimulus.

Now let us take notice of a pathological stimulus. We need to keep in mind two hypotheses: first, that the stimulus which causes exophthalmic goitre is situated without the gland and secondly, that this stimulus induces changes in the gland which in turn cause the manifestations which we recognize as the signs and symptoms of the disease. Some may not agree with this statement if so the argument must come later. The stimuli which induce these changes may be active from beginning to end of the disease. There is a time early in the disease when these stimuli urge the gland intensely and there comes a time when they lessen in their intensity, but when the results induced by them in the thyroid gland dominate the clinical picture. This has to be borne in mind in deciding the treatment to be followed at the different stages of the disease. Possibly the stimulus is a subconscious sex disturbance, possibly some psychic trauma, possibly focal sepsis is added, and possibly there is deficiency of available iodine. If that pathological stimulus is directed on to a normal gland the whole gland is able to respond, it changes into a solid cellular organ—the gland of a primary exophthalmic goitre—and we have the signs and symptoms of a primary exophthalmic goitre. If that pathological stimulus is directed on to a gland in which post-puberty involution has not occurred—in other words on to an early colloid goitre—the whole gland cannot respond, cannot change into a solid cellular organ for most of it already consists of enlarged colloid vesicles and the only parts of it which can respond to the abnormal stimulation are the cellular areas between the vesicles. These scattered areas become solid, opaque, whitish, and similar to the whole gland in the primary exophthalmic case. Both these types are quite definitely exophthalmic goitre. Both have prominent eyes, a hot skin, tremor, a rapid pulse, and both follow a similar course. Why separate them? Only because the appearance of the gland, macroscopically as well as microscopically, is so different, and because the second type links up with the late secondary type, and may help to explain the late toxic nodular goitre.

Now take late secondary Graves's disease. In this we have a woman who has had a goitre for many years. We know from our own experiences that the colloid goitre of puberty about the third decade loses its smooth surface and becomes nodular. It is still symmetrical, but fibrous strands develop, constricting and isolating areas throughout the gland. In the woman who "has had a goitre all her life" this change has been progressing until the fifth decade. How does this condition become toxic? The same factors which affect a younger woman with a normal gland giving her frank exophthalmic goitre, or another woman with an early colloid goitre, giving her early secondary Graves's disease can be brought into action at any time during a woman's life but if these factors are directed on to an old fibrotic goitre the areas in it which are able to respond are small and scattered. We cannot at this stage expect the whole gland to respond as the normal gland did which produced exophthalmic goitre, or even as the early colloid goitre responded, and so we get a

condition with which we all are familiar—although it may be given different names by different observers—the late secondary Graves's disease. This is included by Plummer under the term "toxic adenoma." Both pathologically and clinically we find every gradation between this and exophthalmic goitre, and between it and true toxic adenoma. This pathological change may be scattered throughout the whole gland, but we may see it limited to one lobe, replacing all the normal tissue of that lobe, the other lobe remaining, as far as we can tell, normal. Again, we see occasionally one single adenoma, the removal of which frees the patient from her symptoms, and therefore we must believe that it alone was the cause of the manifestation of disease from which she suffered.

There are thus three important factors concerned in the manifestation of exophthalmic goitre, and each of these may vary within wide limits, with corresponding differences in the ultimate result to the patient.

- 1 The stimulus directed on to the thyroid gland
- 2 The thyroid gland which in responding to the stimulus produces disordered secretion
- 3 The heart muscle (leaving out of count other viscera for the moment)

I have stated what I believe this stimulus to be. It may be intense and soul-racking, or less intense but unceasing. It may be directed on to the mechanism of a thyroid gland which is normal, or which is in a condition of colloid or adenomatous enlargement with fibrosis. The response of the thyroid gland to the stimulus may result in secretion which affects a heart whose musculature is unimpaired, and therefore able to stand up to years of intoxication, or whose musculature is already affected by the wear and tear of life and on this account soon feels the effect of an added thyrotoxaemia.

The place of surgery in the treatment of toxic goitre will vary in each of the conditions which have been discussed. Some may question whether surgery has any place in treatment. Kessell, Lieb, and Hyman<sup>1</sup> report that with skilful neglect the prognosis is excellent. Barber<sup>2</sup> has stated that the course of the disease associated with diffuse hyperplasia of the whole gland—that is, primary Graves's disease—"is probably two or three years, no matter how you treat it (medically, surgically, or radiologically)." My answer to that is, that of 273 patients operated upon by me consecutively in the last few years, 107 had suffered from the disease over four years, 77 over six years, and 53 over ten years. This represents much unhappiness for patients and their relatives, and great economic loss.

One other important question is, Could the disease have been arrested earlier? My medical colleagues will bear me out that, while patients have been lying in bed in hospital wards under what we must regard as efficient treatment, most disturbing features have developed, and it has been impossible to arrest the progress of these by any means with which we are familiar. I mean by this that corneal ulceration has occurred while the patient has been at complete rest. In several patients destruction of an eye has occurred. In one patient this lit up the other symptoms, which at the moment were not progressive, to such an extent that the patient died. Glycosuria has developed in others, maniacal symptoms in others again. Loss of weight frequently occurs in patients who have been in bed for months—5 st in one patient—and auricular fibrillation has developed in patients who were under observation.

Again, take the economic factor. For the moment we may leave out of the discussion the question as to whether, if all patients were treated under ideal conditions, the disease could be arrested or controlled. We are faced with the fact that many patients are gravely ill, and have been ill for a long time, and that in the stage in which we find them they cannot be restored to an industrial plane by medical means, using medical means in its broadest sense. For these two reasons surgery has a place in the treatment of toxic goitre, if we can show that it is able to arrest the disease and permit a patient to resume life on an industrial plane. What this place should be can only be decided for each individual, after the character of onset,

the stage of the disease, the quality of the gland and the previous treatment, and the social position of the patient have been taken into consideration.

If an operation has to be performed, three important points have to be decided: (1) When should it be performed? (2) How can it be made safe? (3) How can we ensure that it will achieve the object for which it is performed?

Lack of time prevents more than a rapid answer to these three questions. Taking the first—When should operation be performed?—we need to keep the types of the disease in our minds. In a primary case operation should not be performed early. Surely some people never get this disease but successfully resist it. Others get it slightly and recover. Our medical colleagues pilot many of these patients back to health. Some will not be restored to health and will settle into a chronic condition. It would obviously be wrong to operate while there is a chance of recovery without operation. The thyroid gland is much too important to have a great part of it removed unless the necessity is pressing. When a patient has suffered from the disease for approximately six months the question of operation is certainly arguable, and the patient's social position looms largely among the factors upon which we must decide. A well-to-do patient may be willing to live a sheltered life and to give up many activities. The poor patient is in quite another category. She may be unmarried and dependent on her own exertions for her living. She may be married and have a husband and children dependent upon her for the maintenance of their home. Patients in this condition cannot rest indefinitely. I find that what generally happens is that they are taken into hospital for a few weeks or a few months, and then discharged, perhaps a little better, but often much in the same condition as when admitted. Crises occur from time to time, and the tendency is for the patient gradually to sink to a lower plane of health. For these reasons is most helpful. Even the well-to-do patient usually realizes the limitations under which she must live now, in any circumstances, in a certain number the disease progresses, and the signs and symptoms become so aggravated that operation becomes advisable.

When auricular fibrillation has been established or congestive heart failure has occurred, the question has ceased to be arguable. Neither rest nor medical or x-ray treatment will avail to restore the patient to health. These conditions may occur either as a late result of primary Graves's disease or quite early in a case of late secondary Graves's disease, or so-called toxic adenoma. Without operation the patient is doomed to permanent invalidism, by means of operation—followed by treatment—the fibrillating heart is almost always restored to normal rhythm, and congestive heart almost always disappears. In these two types, with auricular fibrillation, there should be no delay beyond the time necessary to get the patient into the best condition for undergoing operation.

The second question is, How can operation be made safe? By ensuring that the patient has no other lead to carry besides the disease itself. It is surprising to what extent patients are still sent for operation with foci of gross sepsis present. The majority of patients improve obviously when septic foci are cleaned up, and in an operation where the margin of safety is narrow enough every factor which reduces this margin should be eliminated. It should not be necessary to insist on this at this late period.

2 By rest in bed. It takes several days for the pulse rate to come down to its resting level when a patient is put to bed and freed from her worries.

3 With exophthalmic goitre, by iodine medication. This should be commenced as soon as it is seen to what extent the pulse rate has dropped as the result of rest and mental relief—that is, usually about the third day. Generally iodine will not only further reduce the pulse rate, but the associated improvement in the patient's condition, but it will induce a definite change in the pathological condition of the gland which makes the operation safer.

4 By confidence between patient and surgeon. It is not enough that confidence has been established between patient and physician. On the operation morning the surgeon must come as a friend, not as a person to be feared. This is not an emergency operation.

5 By adjusting the amount done at one operation to the patient's strength. This is most important, and the surgeon must be able to gauge it. It is always tempting to cut time and get the complete job done in one operation. The patient who has been ill for a long time will often plead for it to be finished at once, and for the surgeon it is vastly easier to deal with the second lobe in a field unhampered by scar tissue. Sometimes this is possible and, if so, it is the right thing to do, but unless the surgeon can judge this, he will tell the patient in the beginning that two operations are necessary and then do at one stage only what is within her strength. If the patient is forewarned she is not disappointed. If she is tacitly allowed to believe that one operation will cure her, and after this is done learns that another is necessary, she will be disappointed.

In dealing with patients with grossly incompetent heart, dilated and irregular, and with oedema, safety is only attained by the closest co-operation between physician and surgeon. In this class the results obtained are surprisingly good (I will present evidence of this later), but the margin of safety is very narrow.

Anesthesia must be considered. Chloroform is unsafe. Open ether is safe but it is a nuisance to have a mask so close to the operation field. Gas and oxygen with a little ether, given by the endotracheal method, is safe, and interferes less with the surgeon than any other method of inhalation anesthesia. Rectal ether is quite good. If the surgeon will take the trouble and allow the necessary time before the operation, local anesthesia gives a comfort in working and a freedom from bleeding which is attained in no other way. Freedom from bleeding saves much time at the operation, and this saving of time, as well as the diminished loss of blood, is of importance to the patient. In cases of auricular fibrillation I believe that local anesthesia is essential. If these precautions are taken, there are few patients who cannot be carried through operation with a reasonable degree of safety, but no consideration of urgency on the part of the patient, or convenience on the part of the surgeon, should ever tempt him to operate at a time other than that which is the optimum, taking all the factors into account.

I think this is the place to speak of the death rate which for this operation will range within wide limits. It will vary according to the type of patients operated upon and greatly according to the time selected for the operation in each individual and the care with which the preliminary treatment has been carried out. Some surgeons will be careful for their statistics, others will undertake operation at some risk on patients who without operation are, so far as can be judged, doomed to complete ruin, and it will naturally vary according to the experience of the operator. My own death rate in operations for Graves's disease—excluding toxic adenoma—is 2.8 per cent. Never neglect this when discussing the question of operation with patients.

Apart from death two other calamities can occur as the result of operation: damage to the recurrent laryngeal nerve, and tetany. I have injured one nerve very occasionally, but I have seen two patients in whom both nerves had been irreversibly damaged. I have had one case of severe tetany.

The third question is: How can we ensure that operation will achieve the object for which it is performed?

There are many patients who have been operated upon for exophthalmic goitre who are not cured, and the reasons for this require examination. Kocher stated that removal of one lobe with the isthmus, and ligation of an artery on the other side, cured 83 per cent of cases. Similar statements were published by American surgeons. Twenty years ago I insisted that this was not so, and I have insisted continuously since. The remaining lobe is bigger than the whole normal gland, and very toxic. It is not reasonable to suppose that the patient could be cured while all this remains. This must be realized in the beginning. The removal of the first lobe is comparatively easy. Removal of the appropriate amount of the second lobe is much more difficult. The approach is through scar tissue, anatomical planes may have been destroyed by adhesions, and an extremely vascular gland must be cut through, but rules

the surgeon is prepared to undertake the second operation he should never perform the first. Removal of one lobe improves a patient so much at first that patient and surgeon are pleased, but this result is so far short of a cure that, if left at that, it can only bring the operation into discredit. The pulse rate will not remain down, the eyes will not recede, and in patients with auricular fibrillation there will not be restoration to normal rhythm. To make the operation effective sufficient gland substance must be removed to eliminate the toxic effects of the secretion, always bearing in mind the physiological needs of the body.

What evidence can we produce that surgical treatment will shorten the duration of the disease, or restore to normal function organs which have shown evidence of failure? I have selected some cases to illustrate different grades of the disease and the response to operative treatment in each.

Two young women had both been ill for more than six months, but had no heart failure; one of them earned her living by working in the General Post Office, the other had difficult home duties. The first went back to her work at the post office immediately on her return from convalescent home four years ago and has worked continuously since. She feels quite well. The second, whose exophthalmos was such that she suffered from corneal ulcers each time, was in hospital sent home to nurse an invalid father who apart from her day work, kept her out of bed several times each night. She writes to state that she feels well and carries out her duties without difficulty. A German on the northern export service went back to his duties after his return from convalescent home and has carried on continuously since.

**Exophthalmos**—The question is often asked: Will the eyes improve? They will. How much we cannot say. Sometimes the return to normal is not so complete, but there is always much improvement, and this improvement increases.

**Cardiac Failure**—Now we pass to patients with cardiac failure. These are the patients about whom Marion Read<sup>4</sup> writes: "Many had reached the stage of myocardial damage which leads to decompensation, which is the one residuum of this disease which is most distressing and from which there is often no recovery." This statement has been much quoted. I have operated upon 63 patients with established auricular fibrillation in the last six and a half years. Some of these could only be described as waterlogged wrecks. Of them 4 have died, 4 have, for one reason or another, only had one lobe removed and the heart beat has not regained normal rhythm, of the other 55 I believe only 2 have not regained normal rhythm. Therefore 87 per cent of these patients have been restored to a level of health which could scarcely have been believed possible. In reference to these deaths, some of the transformations have been so remarkable that we are occasionally lured into attempting too much, but I believe that in this type of case the death rate has not been higher than has occurred in cases not operated upon. The disappearance of fibrillation is interesting in another respect. We do not yet know the origin of this disease, but the disappearance of fibrillation after operation shows that the origin of the toxins which are the ultimate cause of some of the most distressing symptoms is in the diseased thyroid gland.

**Glycosuria**—In working with my medical colleagues it has become clear that with some patients who have suffered from glycosuria associated with Graves's disease it has been impossible to control the glycosuria before operation, while after a sufficient thyroidectomy the glycosuria has disappeared spontaneously or has been readily controlled.

**Dropy**—The following case illustrates the increase in the amount of urine immediately following operation in a waterlogged patient in whom diuretics had been ineffective.

A woman arrived from South Africa as ill as a patient could be. Legs, thigh and trunk were enormously increased in size—a finger would leave a pit anywhere below the level of the breasts—the abdomen and pleural cavities contained fluid. She was dyspnoeic and the daily amount of urine passed was little over one pint. The heart beat was irregular for five years. She was kept for a month while every effort was made to increase the urine, decrease the drops, and lessen her breathlessness. She was worse rather than better at the end of the month and then one lobe was removed. In three days the urine output increased to 60 oz. and then to 90 oz. The oedema disappeared synchronously with this. Part of

the second lobe was removed later. She went back to South Africa by herself. She now camps out, rides on horseback, and manages her household affairs.

One further aspect remains to be spoken of—namely, mental disorder. This complication is not common, but, taking a large number of cases, it is not infrequent. Some patients have suddenly become maniacal and died. I have had to decide what course to follow in patients who were gradually getting worse and who were approaching, or had reached, a stage when they could not be managed in their own homes. I have never operated upon these patients without the fullest consultation, and without the relatives appreciating all that is at stake, and sometimes a patient is too ill to justify operation. It is wise to have the help of a specialist in mental disorders before a decision is arrived at. Only one of these patients has not improved, the others have, after operation, returned to their ordinary way of living. One of them has married since, and one of the worst was driving her own car around London within eight weeks of her second operation.

The degree of recovery in these cases, and in the majority of cases, appears to be very high, and yet I think we must believe that in Graves's disease the secretion is not normal secretion, and when we reduce its amount by four-fifths we are not leaving a patient with an output of secretion normal in amount and quality, and therefore the end-results are not strictly comparable with those obtained after removal of a diseased appendix.

**Anorexia, with Emaciation.**—Now the other side of the picture. I have had three patients who have suffered from extreme anorexia—an unusual symptom in Graves's disease—associated with great wasting. The emaciation, as you know, is frequent, the anorexia is not, and I cannot help thinking that some factor with which we are not familiar is present. Of these three, one recovered after operation, one is just about holding her own, and one died some months subsequently.

Patients who have suffered severely from exophthalmic goitre never become normal as they were before the disease occurred, but they are a great deal nearer normal than if they had not been operated upon, and almost all of them can take up their work and enjoy life in the world once more.

I would ask you to bear in mind two points. We must visualize a heart and nervous system flooded with toxic secretion, sometimes continued for years. If that toxic secretion is suddenly reduced by four-fifths, the organs quickly show relief—often, indeed, dramatically—but it is unreasonable to expect that their complete recovery (their capacity to stand up to strain) should be other than gradual, and may never be quite complete. My second point is, that as soon as a sufficient operation is performed the patient feels a different woman, and is on an up grade all the time. She is conscious of this herself, and it is obvious to her friends.

## II—INDICATIONS FOR SURGICAL TREATMENT IN TOXIC GOITRE

BY

GEORGE R. MURRAY, D.L., M.D., D.C.L., F.R.C.P.,  
Emeritus Professor of Medicine in the University of Manchester,  
Consulting Physician to the Royal Victoria Infirmary, Newcastle,  
and to the Manchester Royal Infirmary.

It is important to regard the surgical treatment of toxic goitre from three points of view. When the question of an operation is under consideration it is advisable to take the opinion of the physician, of the surgeon, and of the anaesthetist, if possible in consultation, in deciding whether medical treatment should be continued or surgical treatment be adopted forthwith. The term "toxic goitre" includes all forms of goitre which give rise to general symptoms, is distinct from those which cause only disfigurement of the neck or pressure on neighbouring structures. These general or toxic symptoms are due either to

hyperthyroidism or to dysthyroidism—in other words they are the result of the passage from the goitre into the blood either of an excessive amount of normal thyroid secretion or of an altered secretion.

As the relative importance of changes in the quantity, as compared with those in the quality, of thyroid secretion in the production of thyrotoxicosis is still open to discussion, the term "hyperthyroidism" will be used simply to indicate overactivity of thyroid secretion in whatever form it may ultimately be proved to occur.

In considering the indications for surgical treatment in this group of maladies we require some form of classification. Mr. Dunhill has given us a valuable lead in this respect from the surgical aspect. I find that rather a different arrangement is more convenient from the medical point of view, as the physician sees early and mild forms of toxic goitre, in which the question of operation does not arise. A physician is apt to feel that all cases of toxic goitre ought to be amenable to medical treatment—is, indeed, we hope in the future they will be—and so is liable to look upon the necessity for surgical treatment as a confession of failure. There are, however, certain forms and stages of toxic goitre in which an operation at present affords the only means of cure or relief of the malady.

### CLASSIFICATION

I find the following classification is useful for practical purposes, but it must be clearly understood that there is no sharp line dividing the different groups, as intermediate cases occur.

In the first place it is advisable to divide all forms of toxic goitre into (a) primary, and (b) secondary groups. In the primary group may be placed all cases in which the onset of the toxic symptoms either precedes or coincides with the appearance of the goitre. In the secondary group the toxic symptoms only develop after a goitre, of one kind or another, has been present for several years without causing ill health. It is in this secondary group that surgical treatment is most frequently required. There are two forms of primary toxic goitre: (1) simple hyperthyroidism (thyrotoxicosis), (2) exophthalmic goitre. There are three forms of secondary toxic goitre, which may be conveniently called: (3) simple secondary hyperthyroidism (thyrotoxicosis), (4) toxic adenoma, (5) secondary exophthalmic goitre. I shall now endeavour to describe briefly these five forms of toxic goitre, with special reference to the indications for surgical treatment in each of them. Brief details of a few cases will be given as examples.

### PRIMARY TOXIC GOITRE

#### 1 Simple Primary Hyperthyroidism or Thyrotoxicosis

In this condition the thyroid gland is enlarged to a slight or moderate degree. In some rare cases the toxic symptoms precede any palpable enlargement of the gland. The pulse rate at rest is increased to 80, 100, or more, and is easily accelerated by exertion or emotion. The mind is alert, and the hands tremble when extended. The skin is warm and moist, there is loss of weight, and gastric or intestinal symptoms may be present. The basal metabolic rate may be increased by as much as 50 per cent. This form of toxic goitre corresponds to the "formes frustes" of the French writers, and may be illustrated by the following case.

Miss R., aged 26, complains of palpitation on exertion, nausea with occasional vomiting, perspiration, and nervousness. There is a uniform goitre of moderate size but no pre-tibial oedema. Pulse 100 to 104, no cardiac murmur, fine tremor, no exophthalmos. Medical treatment advised.

These patients are not seriously ill, they are usually amenable to medical treatment, and so are seldom referred to a surgeon. Occasionally a patient gets progressively worse, the pulse rate increases to 120 or more, the hands enlarge and may begin to fibrillate, there is great loss of weight, and severe gastro-intestinal symptoms may supervene. In these circumstances, even when the thyroid is not enlarged or not even palpably enlarged, an operation should be carried out without delay. It is not sufficiently realized that serious thyrotoxicosis may occur, and even end fatally, while external examination fails to reveal any enlargement.

of the gland the true nature of the malady only being revealed by the microscopical examination of the gland after death.

## 2 Primary Exophthalmic Goitre

In mild and moderately severe exophthalmic goitre medical treatment alone suffices in the majority of cases and should be given a fair trial for at least six months before it is abandoned in favour of an operation.

In a series of cases of exophthalmic goitre of all grades of severity under my care at the Manchester Royal Infirmary a thyroidectomy was performed in one-twelfth, as medical treatment had failed. In a few cases owing to the urgent necessity of earning a living or of removing to some remote part of the world, an immediate operation has been advised which in other circumstances would have been postponed. In some cases this course has proved successful in every way but there is a greater risk of a death which might have been averted if time and circumstances had allowed for prolonged medical treatment.

In a large majority of cases of Graves's disease the enlargement of the thyroid is only slight or moderate, and there are no pressure signs. In a few cases, however, the goitre is larger than usual. In these medical treatment is apt to fail so that even if pressure signs are entirely absent an early and extensive thyroidectomy is advisable. In all cases in which no decided improvement has taken place during six months of medical treatment the advisability of surgical treatment should be fully considered. In the physician and surgeon in co-operation. In selecting a surgeon it must be realized that special experience and certainty are just as important in a thyroidectomy as in a parathyroidectomy or in any laryngeal operation.

One of the chief dangers to life in prolonged cases of exophthalmic goitre is due to the development of thyrotoxic myocarditis so that in cases in which medical treatment fails to prevent the onset of early signs of cardiac failure an operation should not be delayed. In the past an operation has frequently been considered too hazardous in certain cases to be undertaken in these cases, but thanks to the work of Professor Fraser and Mr Dunhill we now know that signs of myocardial failure, such as auricular fibrillation and oedema of the legs are not a bar to operation but rather an indication that it should be carried out as soon as the patient has been prepared by medical treatment so as to minimize the risk of it as far as possible. In the case as in all forms of thyrotoxic myocarditis it is important to realize the danger of delay as it is not fair to the surgeon to wait until the signs of cardiac failure are advanced before asking him to see the case with a view to operation.

Briefly the advantages of operation in primary Graves's disease are: (1) The saving of time owing to the prompt reduction of the thyrotoxicosis and immediate relief of symptoms. (2) The complete recovery in some cases and marked improvement in others. (3) The diminution of the risk of the development of chronic myocarditis.

The disadvantages are: (1) The risk to life. (2) The uncertainty of the ultimate result on the operation owing to the difficulty in determining the right amount of the gland which should be removed in each case. (3) The tendency to recurrence within a year or two, with the necessity for further medical or surgical treatment.

The following case illustrates recovery after operation.

Ms M aged 27 seen February 14th 1921. Eighteen months duration. Physical signs. Moderate uniform goitre pulse 150 enlarged heart exophthalmos tremors. As this patient was very anxious to accompany her husband who was going to live in China at an altitude of some 7000 feet above sea level and was Mayo Clinic for an operation. In the following June Dr V C Hunt ligated both superior thyroid arteries. This was followed in September by a second removal of the gland with removal of the isthmus. She was able to proceed to Japan in November and the last report received from her there stated that she was quite well.

The following cases illustrate the tendency to recurrence after operation.

Ms L A severe case of primary exophthalmic goitre in which the symptom had developed acutely after a long visit to a dental surgeon. First and medical treatment failed to relieve her. On two occasions a partial thyroidectomy was carried out by Sir Victor Horsley with benefit but when I saw her again

after an interval of ten years the symptoms were still well marked. They then subsided under x-ray treatment.

Mr F B aged 41. Symptoms of exophthalmic goitre first developed in 1923. In 1914 a partial thyroidectomy was performed by Mr Kelly of Liverpool. Improvement followed so that he was able to follow his occupation for the next ten years. When seen for the first time in 1925 the right lobe of the thyroid was absent and the left lobe had increased in size during the previous twelve months. Pulse 140 to 160 well marked exophthalmos tremors pigmentation of the skin glycosuria.

## SECONDARY TOXIC GOITRE

### 3 Secondary Simple Hyperthyroidism or Thyrotoxicosis

In this group may be placed cases in which a simple colloid or parenchymatous goitre of several years' duration becomes toxic. This complication may arise, either gradually or rapidly as a result of some emotional strain or for no apparent reason, long after the goitre first appeared. The symptoms are the same as in the primary form. The following are illustrative cases.

Miss P aged 33 teacher. Duration of goitre long but uncertain as the neck had always been full. A definite swelling had appeared during the last month. For a year he had found her work too hard for her. She had vomited several times and had lost weight. Physical signs. Moderate uniform goitre with thrill and bruit pulse 120 heart apex beat in left nipple line systolic murmur at apex and over pulmonary area slight eccentric widening of palpebral fissures and pigmentation of eyelids but no exophthalmos. Medical treatment advised.

Miss R aged 43 teacher. Seen June 1st 1927. A goitre had been present for at least twenty-three years. She had recently lost her father mother and brother. Six months ago she suffered from erythema nodosum. For the last five months she had had palpitations and tremors with icterus and diarrhoea at times. Physical signs. There is a uniform soft goitre of moderate size the circumference of the neck being 16 in. pulse 140 systolic blood pressure 150 mm diastolic blood pressure 100 mm tremors moist skin and some loss of hair increased frequency of defaecation menses irregular. Medical treatment advised.

In these cases medical treatment may in the absence of urgent symptoms, be given a fair trial. The results are not so good as in primary hyperthyroidism but the toxic symptoms may subside, although the goitre will persist even if it is reduced in size. If there are no marked results from medical treatment in three months a thyroidectomy should be advised.

### 4 Toxic Adenoma

The term "toxic adenoma" has been used with a varying significance by different authors. Some include the group which I have just described, but it seems best to restrict the name to those cases in which a nodular goitre—that is to say, an adenomatous or adenoparenchymatous goitre, which may be cystic—has been present for some time even many years, before the toxic symptoms appeared. The cardio-vascular symptoms are often prominent in these cases though wasting nervousness tremors and gastro-intestinal symptoms may also be severe. The following are records of cases in this group.

Ms H aged 41 seen January 3rd 1926. A goitre had been present for eight years. She had not been well since an attack of diphtheria after which she lost 2 st in weight. The right lobe of the thyroid was moderately enlarged and firm in consistency but there were no pressure signs. Pulse 124 systolic blood pressure 105 mm heart apex beat in left nipple line. Nervousness and tremors were present but there were no eye signs. Menses regular. At operation on February 2nd 1926 Mr Burgess removed a large deeply buried adenoma of the right lobe. On examination by Dr Loveday this showed the structure of a fibro-adenomatous goitre. In some parts there was an atrophic condition with fibrosis and haemorrhage and in others marked adenomatous proliferation of the acini and some mucoid degeneration. Here and there an acinus was seen with columnar cell formation. On June 15th 1927 Dr Leather reported that the patient was very well. When last examined early in the year the pulse was 70 to 80 never exceeding the latter she was much less nervous and there were no tremors. She had gained 2 st in weight and the hair had begun to grow again.

Ms H aged 40 seen February 11th 1925. There probably had been some enlargement of the thyroid gland since childhood but during the last five years the left lobe had been definitely enlarged. For several years she had felt tired by mid-day. She had suffered from bronchitis and had been worried by her business. Recently she had a course of treatment during which took one tablet of Crookes' colloidal iodine 1 per cent thrice daily and she had three doses of x-rays. Or later he had lost weight the pulse frequency had increased and tremors were present. There was a uniform goitre with a small central adenoma. There were no pressure signs or eye signs. Pulse 130 to 140 irregular owing to auricular fibrillation heart apex beat in left nipple line. Defaecation four or five times a day. Operation was advised after a preliminary course of digitalis. About

a fortnight later the left lobe and isthmus of the thyroid were removed by Dr Crug of Kendal, ether being given by the rectum. The patient made an excellent recovery and Dr Crug recently informed me that she had gained 5 st in weight, the pulse was regular and not more than 88 even after a hard day at business. The tremors and nervous symptoms had entirely disappeared. She still finds that she cannot hurry or climb hills without some dyspnoea, but this is the only symptom left of the severe thyrotoxic myocarditis which was present when I saw her before the operation.

In the following case medical treatment was adopted, as the patient had a young family, and did not wish to run the risk of an operation.

Mrs X had had a goitre for fourteen years. She complained of feeling tired at times of loss of weight, throbbing in the neck, and of palpitation, especially during the last three months. There was a moderate uniform enlargement of both lobes of the thyroid with a small central adenoma the size of a cherry. Pulse 120, heart apex beat in left nipple line. Tremors were present.

In cases of true toxic adenoma operative treatment is advisable as soon as the symptoms become moderately severe, as medical treatment is of little permanent value. In a few cases in which operation has been declined or postponed and medical treatment has been continued some diminution of the toxic symptoms has followed x-ray and medicinal treatment, although there has been no diminution in the size of the goitre, but such improvement is apt to be of short duration.

### 5 Secondary Exophthalmic Goitre

A convenient group is formed by all the cases in which the goitre has been present for several years before the onset of Graves's disease. In order to save further subdivision these cases may be grouped together whatever the character of the pre-existing goitre. In these cases exophthalmos and the other characteristic symptoms of Graves's disease are present. Secondary exophthalmic goitre is not common in this country; in a series of 300 cases seen by me in private practice only twelve were secondary. It is not so amenable to medical treatment as the primary form of the malady. In the majority of the cases, especially when the goitre is either large or nodular, an operation should be advised as soon as the symptoms are well marked. If this cannot be carried out medical treatment must perforce be continued, but the results are disappointing and myocardial changes are only too prone to progress to complete invalidism or to a fatal termination.

Mrs H, aged 57, first noticed that she had a goitre twenty years ago, this diminished in size after the application of iodine paint. Three years ago she began to feel tired and suffered from palpitation and insomnia. The weight decreased from 9 st 3 lb to 7 st. There was a cystic and adenomatous goitre. Pulse 140, slightly irregular, blood pressure 170/60, heart apex beat heaving, external to nipple line, loud mitral systolic murmur, slight exophthalmos, tremors. A suitable case for operation.

There is one special form of goitre in which, though it is truly toxic, the symptoms are not due to hyperthyroidism. I refer to the septic goitre in which an adenoma or cyst becomes infected and gives rise to a general toxæmia. I have recorded such a case in which infection of an old cystic goitre by the colon bacillus caused an intense toxæmia, which promptly subsided when the pus and gas were removed. The treatment of these cases is purely surgical.

There is no doubt that in some cases of toxic goitre focal sepsis plays a part in starting or in aggravating the thyrotoxicosis, either by way of a subinfection or a toxæmia. In my own experience the frequency and importance of focal sepsis has not been nearly so great as has been stated by some writers. In every case, however, a careful search must be made, and if a septic focus is found it must be dealt with by surgical means appropriate to its situation.

The type of operation and the choice of the anaesthetic must, of course, be left to the discretion of the surgeon and the anaesthetist. When surgical treatment has been selected the physician wishes as much of the abnormal gland to be removed as will ensure early improvement and, if possible, cure without recurrence, enough of the gland being left to prevent the onset of post-operative myxoedema. It is thus no light task we ask the surgeon to perform, but when the ideal result is obtained we are all the more

grateful for what he has done for our patient. From a medical point of view a subtotal thyroidectomy in which seven-eighths of the goitre are removed at once appears to be the most desirable procedure in the majority of cases. After the modern methods of preparation of the patient in which medical treatment plays such an important part, preliminary ligation of the thyroid arteries and piecemeal operations should seldom be necessary. Finally it must be remembered that, in some cases, although marked improvement follows the operation, the patient is still far from being well and may still require medical treatment for a considerable period before recovery takes place.

### DISCUSSION

Mr C THURSTAN HOLLAND (Liverpool) related the case of a deeply jaundiced, wasted, vomiting woman, to whom an operation had been refused by a surgeon, x-rays cured her. He believed many patients treated by surgery could have been benefited by x-rays. They should always be used in early cases, and in advanced cases astonishing results occurred. The mortality was nil. X-ray burns and telangiectases should never be caused. He did not think myxoedema resulted from the use of x-rays.

Professor R E KEENE (Liverpool) pleaded for intratracheal anaesthesia. An x-ray photograph, to show the position of the trachea, was useful. Warming the ether vapour was unnecessary, though moistening was advantageous. Toxic adenomatous patients were very susceptible to morphine. Iodine should be given for one week before operation upon true exophthalmic goitre. Though the early case with symmetrical enlargement was much improved by iodine administration the patient with adenoma and hyperthyroidism did not respond to anything like the same extent.

Dr JOHN EISON (Edinburgh) stressed the importance of primary exophthalmic goitre. Death, in the vast majority of cases, was remote. Early operation restored a patient to normal function and stopped the deterioration of important organs. He thought operation probably raised the general death rate, when, however, deterioration of important organs had set in, operation should be considered. He desired evidence of early operative mortality. Most young people with exophthalmic goitre adjusted themselves to ordinary life activities. He regarded the general policy of operation as wrong, to justify surgical intervention the risk of deterioration must be obvious or medical treatment be unobtainable.

Sir W DE COURCY WHITLAW (Dublin) said that in estimating the effects of various treatments it was necessary to remember that the disease was one of cycles, normal improvement during one of the cycles could be hastened by x-rays and the administration of iodine. Recurrence of crises, he believed, could only be certainly prevented by a thorough surgical operation. Of 80 patients, all of whom were definitely toxic, every one had had medical treatment, with or without x-rays, for months or years before seeking surgical help because the cures were of a transitory nature. Iodine was very potent generally in bringing about temporary improvement. He thought that the common adenomatous goitres of women were made toxic by the administration of iodine, and the effect upon the cardiovascular system was often disastrous. The effect of iodine in true goitres was admirable and dramatic in about half the cases. In about one-third some improvement was noticed and in the rest there was no obvious effect. He had cured a patient with Graves's disease become very much improved with iodine. The mortality of operation in early cases was almost nil. He employed rectal anaesthesia combined with a local anaesthetic, a few patients had been anaesthetized only.

Mr JOHN MORLEY (Manchester) said that surgery and x-rays alone had no effect upon true primary Graves's disease, the former brought about much more rapid improvement than x-ray treatment. The mortality had been lowered very much of late years, and Lugol's solution

had helped a great deal. The operation should be performed seven to fourteen days after the institution of iodine therapy, seven eighths of the gland should be removed. Preliminary ligaturing of the arteries had not proved satisfactory and therefore the whole operation should be performed at one sitting. X rays were apt to leave cardiac disturbance unaffected.

Mr A J WALTON (London) said that advanced colloid goitre it is persisted to middle life changed to diffuse adenomatous goitre. This kind of goitre rarely gave rise to exophthalmic symptoms. The exophthalmic goitre was rare in type in young people and nervous in type in older women about the menopause. Operation often failed to relieve this second group. He believed the medical mortality to be pretty considerable. X rays had no effect at all upon the disease in his experience though they performed wonders in carcinoma of the thyroid. He had never seen fibrosis of the thyroid after exposure to x rays. Lugol's solution was excellent as a preliminary drug.

Dr L A ROWDEN (Leeds) said that in twenty years only seven cases of toxic goitre had been operated upon at Leeds. All the other cases had been referred to the radiographer as the surgeons in this town regarded x ray treatment as the method of choice. If the full effect were to be obtained by this means it was necessary to give such doses that the skin was bound to be damaged. He had had experience of 550 patients severe cases recent cases cases with high basal metabolic rate and cases with small glands did best. He strongly advocated x-ray treatment.

Dr F A C STARR (Toronto) said that he had consulted his records for 1926, and with his assistants he had committed during that year 253 benign offences according to Mr Holland. He had given up advising x rays or radium treatment which did no good in the adenomas whether hyperplastic or simple, and was dangerous in the diffuse hyperplastic. In ten cases treated some years previously the two last patients had succumbed within a few hours after the first x-ray treatment. With really all patients the cure was so long delayed that it was not worth while subjecting them to the misery of six months to a year's treatment when a few weeks would accomplish what x rays failed to do. Dr Starr thought that the goitre problem was changing at least on his side of the Atlantic. Twenty years ago in Toronto there were many non-toxic cases and an occasional case of Graves' disease. Now however the tables were turned. Last year, out of 253 cases operated upon, 27 only were non-toxic and 10 were of the diffuse colloid type with hyperplasia or presented colloid adenoma with a small amount of diffuse hyperplasia. 52 were definite hyperplastic adenomas while 119 were diffuse hyperplastic. Finally, 54 cases, which so far as he knew seemed to be local, were of the diffuse hyperplastic goitre variety with hyperplastic adenomas as well. These last always aroused great concern but after operation the result was spectacular, provided that judgement did not fail and in operation was performed at the psychological moment. A preliminary rest treatment in the hospital was greatly to be preferred to rest at home because often the entire benefit was lost by the journey to the hospital. In addition a minimum of two quarts of water, together with overfeeding and the use of Lugol's solution hastened the improvement. Often when a patient was apprehensive if she could be placed in a two-bed room or in a large ward next to a patient who was convalescing after a very serious illness she would improve more rapidly as the patient who was recovering talked about the great benefits obtained.

Mr CHAS JOYE (London) said there were many patients with adenomatous glands and only slight toxic symptoms and they had been included in many statistics so that confusion had resulted. True exophthalmic goitre showed severe metabolic and nervous disturbances. Symptoms rose and fell in severity in a highly variable and apparently capricious fashion. In the toxic adenoma they were constantly progressive and involved the cardio-vascular apparatus far more than any other systems. He had

never seen true exophthalmic in toxic adenomatous case. Joigne had a good effect on both groups. Surgery was indicated in most patients arising from exophthalmic goitre but shrewd judgement was required in deciding how much gland to remove. Nine tenths of the operation was in toxic adenoma had been removed. The mortality was less in toxic adenomatous cases than in exophthalmic goitre. He had treated 97 per cent of his own cases, and in general the results were good.

Mr DENNIS, in reply said that surgical opinion was gradually becoming rationalized as to the place surgery should take in the treatment of toxic goitre. He did not advocate operation in early cases.

## THE THERAPEUTIC USES OF CALCIUM SALTS

### I—THE PART PLAYED BY CALCIUM IN THE LIVING ORGANISM

FRANCIS P. FRASEP, M.D., F.R.C.P.  
Professor of Medicine St. Bartholomew's Hospital  
University of London

AN understanding of the indications for the administration of calcium in the treatment of disease and of diseased persons is complicated by the fact that this substance is always present in the body. Further it is present in the blood in amounts that are remarkably constant. The serum in health contains about 10 mg per 100 ccm. Variations of from 9 to 12 mg have been recorded by various workers, but some investigators obtain more constant figures. A serum content so constant at this point is due to the presence of some mechanism that maintains a balance between absorption and elimination and deposition which must be taken into account in rational calcium therapy. Further this constancy in the calcium content of the serum in health suggests that it plays an important part in the life of the individual and the relation of the body to its environment.

The source of the body calcium is the calcium in the food ingested. Only a small proportion of the ingested calcium is absorbed most of it being passed from the body in the faeces. The greater part of the absorbed calcium is excreted back into the tissues and eliminated with the faeces but a small fraction is eliminated in the urine. During childhood considerably more is absorbed than is eliminated since much is retained for the proper construction of the bony skeleton.

Our knowledge of the functions of calcium in the living organism is vague and probably scanty at present. Certain facts are however well established. It enters into the mechanism of the clotting of blood and is essential to the mechanism. A low content of calcium in the serum is associated with a disturbance of the neuromuscular apparatus so that the electrical excitability is increased and tetany may result. It appears to be essential to the proper contraction of heart muscle since the perfused heart ceases to beat sooner if calcium salts are absent from the perfusion fluid and beating recommences on the addition of the fluid of a soluble calcium salt. It is an essential constituent of bone.

In addition to these specific functions it plays an important part in the balance of ions in the tissues and fluids of the body. Undoubtedly this ionic balance enters into all of these functional activities that have been specified and disturbances of this balance occur in the abnormal states in which these functions are impaired. It is probable that in many more functional derangements not yet elucidated calcium plays a part though appears in this balance of the ions. A balance between calcium and magnesium ions on the one hand and sodium and potassium ions on the other, has been demonstrated in normal

The opening paper of a discussion in the Section of Therapeutics and Pharmacology at the Annual Meeting of the British Medical Association at Edinburgh 1927. Professor J. A. Gunn presided.

life, and this balance may be disturbed by alterations in the ionic concentrations of any of these elements. The part played by calcium in spasmodophilia and tetany, and in the contraction of heart muscle, must be viewed as exercised through this balance of ions as well as by calcium specifically. For example, calcium is essential to the normal functioning of the neuro-muscular apparatus, but increased electrical excitability may be produced either by a decrease in calcium or by an increase in sodium or potassium.

A balance also exists between the basic ions, such as sodium and calcium, and the acid ions, so that an increase in the acid radicals is accompanied by an increase in basic ions, the balance, upon which the hydrogen-ion concentration depends, being kept almost constant in health. Further, calcium exists in a solid form as  $\text{Ca}_3(\text{PO}_4)_2$  in bone, and a balance must exist between the  $\text{Ca}^{++}$  ions and the  $-\text{PO}_4^{---}$  ions and the solubility of the  $\text{Ca}_3(\text{PO}_4)_2$ , so that the product of ionic concentration cannot rise above a certain level. An increase in the product will cause a deposition of solid  $\text{Ca}_3(\text{PO}_4)_2$ , and a diminution will result in the passage of  $\text{Ca}_3(\text{PO}_4)_2$  from the deposits in the bones into solution in the body fluids. An increase in the concentration of  $\text{PO}_4^{---}$  ions will, however, result in a diminution of  $\text{Ca}^{++}$  ions, the product remaining constant.

These very superficial considerations must suffice to show that disturbances in the specific functions of calcium due to insufficiency are merely symptomatic of abnormalities that may be far-reaching in their consequences and remote in their causation, while any attempt to influence the specific functions by increasing the concentration of calcium above the normal may have effects on important constituents of the body and on remote functions.

#### Serum Calcium

The amount of total calcium in the serum is used as an indication of the calcium supply in the living body. All of this calcium, however, is not in the same condition of chemical combination. The quantity that is in an ionized state has been variously estimated as only 20 to 25 per cent of the total.<sup>6</sup> The work of Salvesen and Linder<sup>6</sup> suggests that part is in combination with protein, and this part will not only be in an an-ionized form but in a non-diffusible form, and therefore not easily available for utilization by the tissues. The diffusible calcium is not easily estimated with accuracy, but from observations by many workers it would appear to constitute 50 to 60 per cent only of the total.<sup>7</sup> Since this diffusible calcium is alone available for producing specific or ionic calcium effects, it is obvious that figures for the total calcium of the serum may not give a true indication of the available calcium. From the work of Vines<sup>8</sup> it would appear that about 4 mg. of calcium per 100 ccm. that was in a non-diffusible form in the whole blood is converted into a diffusible form during the process of clotting. If this is confirmed the figure for the total serum calcium is still further from being a true indication of the available calcium. In considering the significance of departures from the normal values for the calcium content of the serum it is important to remember, therefore, that they may affect (a) the non-diffusible fraction combined with protein, (b) the diffusible and easily ionized fraction, or (c) the ionized fraction. It is possible also that even when normal values for the total calcium are obtained the available calcium may be present in deficient amounts. Until simple and accurate methods are devised for estimating the available calcium in the blood its therapeutic uses cannot be placed on a satisfactory basis.

#### Indications for Calcium Therapy

**Nephritis.**—The total calcium of the serum is definitely reduced in severe nephritis.<sup>9, 10, 11</sup> In the forms with pronounced oedema there is reduction also in the serum proteins, and Salvesen and Linder suggest that the reduction in such cases affects mainly that fraction that is in combination with proteins. They showed<sup>12</sup> that the reduction in calcium and in proteins is not the result of simple dilution, but that there is a reduction in the total proteins of the plasma even after the disappearance of oedema. It is difficult to see how an increase in the serum

calcium, if it could be brought about directly, would of itself be of benefit in this form of nephritis, but a therapeutic measure that would diminish the oedema might well be of benefit to the patient, and might at the same time increase the calcium content of the serum. Blum<sup>13</sup> and his co-workers have advocated the administration of calcium chloride for this purpose, and in his findings and in those of many others it has proved to be an effective diuretic in many cases. It is certain, however, that its action is not due to a specific action of calcium and the restoration of the serum calcium to a higher level. It would appear that it acts by the change that results in the balance of ions in the body fluids. Blum maintains that by increasing the calcium ions the sodium ions are decreased, and since the retention of fluids is closely associated with the retention of sodium, the oedema is decreased. Another explanation, however, is possible. The administration of calcium chloride results in the setting free of  $\text{Cl}^-$  ions, the calcium being retained in or excreted into the intestines as carbonate. The  $\text{Cl}^-$  ions are thus able to cause an increased acidity, and, to correct for this, sodium is excreted as sodium chloride, accompanied by large amounts of water. This latter explanation is supported by the similar beneficial action of ammonium chloride on uric acid. It is, of course, conceivable that the administration of the calcium chloride has some effect from the calcium, as Blum maintains, in addition to its undoubted effect as an acid forming substance. In severe cases of azotemic nephritis the serum calcium is definitely reduced, and this is accompanied by an increase in the inorganic phosphorus of the serum. It seems probable, as de Wesselow<sup>14</sup> has pointed out, that the low calcium content is the result of retention of phosphates and the consequent disturbance in the ionic balance. If, as he suggests, the phosphate retention is directly responsible to some degree for the toxic state known as uraemia, there would be reason to administer calcium to lower the absorption of phosphates. As far as I am aware, no clearly beneficial results have been reported in this form of nephritis by the administration of calcium or by the adoption of any indirect method of raising the calcium content of the serum such as the administration of parathyroid extract.

**Tetany.**—In tetany, following the removal or severe disturbance of the parathyroid glands during the operation of thyroidectomy, the serum calcium is definitely reduced. Tetany is strictly a symptom of a more fundamental disturbance, but is a crippling condition and one dangerous to life. In post-operative tetany it is specifically due to the low calcium content of the body fluids and can be relieved by raising the calcium content. The recent work of Collip<sup>15</sup> has clearly demonstrated the importance of the parathyroid glands in maintaining the calcium at its normal level in the serum, and the administration of extracts of the parathyroid glands, besides being a rational treatment in post-operative tetany, is able to raise the calcium content of the serum and relieve the tetany. There is much evidence of an indirect nature in favour of the view that parathyroid extracts raise the serum calcium by mobilizing the calcium that is stored in the bone and tissues, and that their action does not depend upon the absorption of calcium from the digestive tract. Parrott, Stewart and Percival<sup>16</sup> have reported experimentally to seem to give direct proof of this. The oral administration of calcium salts in excess, however, can raise the level of calcium in the serum and may relieve tetany, and intravenous administration gives prompt but transient relief. In tetany and spasmodophilia accompanying rickets the serum calcium is low. The use of parathyroid extract in rickets is contraindicated, except as an emergency source of increased serum calcium is obtained by the removal of calcium from the bones, which are already deficient in it. In this condition the low calcium could appear to be due to poor absorption, either because of low calcium content of the absence of vitamin D. The low phosphorus content of the serum which is found in rickets is probably an important factor in the defective calcification of the bones. The less constant reduction in calcium in the serum by the loss of calcium salts and cod liver oil will suffice to raise the calcium in the serum to a normal level, but the measures is exposure of the patient, or of the parathyroid

food to sunlight or ultra-violet light may be all that is necessary for the proper treatment of the rickets and the relief of the spasmodic.

**Skin Diseases.**—Low values for the serum calcium have been reported in various skin diseases, such as lupus erythematosus<sup>12</sup> but there is no evidence that the deficiency of calcium is of significance in the pathology of the disease and no clear evidence that raising the calcium level influences the course of the disease.

**Chronic Infections.**—In many and various diseases associated with chronic infections, Grove and Ames<sup>13</sup> find that although the total calcium content of the serum is within physiological limits the amount of active or diffusible calcium is reduced. They further considered that the oral administration of parathyroid extracts and soluble calcium salts was beneficial in these conditions by raising the ratio of active to total calcium. The methods employed by them in their calcium estimations are open to criticism, and the reports of the therapeutic results in their clinical investigations are not convincing. Confirmation of their results is necessary before the scope of calcium therapy can be accepted as embracing the conditions enumerated by them.

**Haemorrhage.**—The administration of calcium has been advocated in many conditions in which there is no evidence of calcium deficiency. The basis for such therapies may be the attempt to obtain an exaggeration of a specific calcium effect, or to correct a disturbed ionic balance. In 1886 Wright<sup>14</sup> advocated the use of calcium chloride administered by the mouth to reduce the prolonged coagulation time seen in haemophilia. Even when the coagulation time is not unduly prolonged, an increased serum calcium has been shown by Matz<sup>15</sup> and Cantarow, Cayen, and Gordon<sup>16</sup> to be associated with a reduction in the coagulation time. Its use has been reported in many cases in which the coagulation time is prolonged, but also in others, such as purpura and pulmonary tuberculosis, in which no such prolongation is found but the results are very irregular and in view of the numerous factors present in patients and the numerous therapeutic procedures that are unavoidably employed at the same time, it is difficult to accept the evidence available as proof of the value of internal calcium therapy to control bleeding. Walters<sup>17</sup> considers that the injections of calcium chloride in the preparation for operation of patients with purpura has reduced the risk of bleeding. I have not yet seen the evidence on which his opinion is based, but it is obvious that careful observations on coagulation time and bleeding time would be of great value, and that there is sufficient ground for the view that there may be a scope for calcium therapy in the control of haemorrhage.

**Myocardial Weakness.**—In 1922 Cheimise<sup>18</sup> reported that his clinical studies suggested that calcium salts by the mouth enhanced the effects of digitalis, making them more rapid in their appearance and enabling a greater beneficial effect to be obtained before the onset of toxic effects. In 1924 Billigheimer<sup>19</sup> found that in normal persons, and in patients with heart failure, calcium chloride intravenously had in action very similar to that of digitalis but that it was more fleeting. He considered that it acts on vagal nerve endings and on the inhibitory centres in the heart. It had no effect on the tachycardia that results from atropine, but checked the acceleration following the injection of adrenaline. There is not at present sufficient evidence for the use of calcium in the treatment of myocardial weakness in patients.

**Inflammatory and other Exudates.**—It has already been mentioned that French workers notably Blum, have pointed out the powerful diuretic action of calcium chloride in nephritic oedema. Blum has shown a similar action in cardiac oedema. That ammonium chloride acts in a similar manner suggests that it is the acid properties of these salts which are responsible for their action as a diuretic, though the calcium may have an effect in the same direction by its antagonistic action to sodium. Blum<sup>20</sup> has extended his observations to inflammatory exudations, and has reported beneficial therapeutic effects in pleural and peritoneal effusions and in inflammation of the conjunctiva. It may be argued that the suppression of inflammatory reaction is not desirable,

except occasionally, when exudations have embarrassing mechanical effects, but Blum's arguments are based on clinical improvement and the disappearance of fever as well as on the absorption of exudates. Based presumably upon this action of calcium ions and of chloride ions on exudations and transudations, beneficial results of the administration of calcium chloride have been reported in such conditions as oedema of the glottis,<sup>21</sup> asthma,<sup>22</sup> oedema of the lung,<sup>23</sup> glomeruloneuritic oedema, urticaria, and Raynaud's disease. If convincing evidence can be brought forward that such beneficial actions are due to calcium, an extensive and important addition will be made to the scope of calcium therapy.

#### Methods of Administration

**Oral.**—Most writers agree that oral administration of calcium salts is inconstant in its effects, and at best produces only a moderate rise in the level of the serum calcium in healthy subjects. The normal calcium requirement for a healthy adult has been variously estimated but the consensus of opinion places it at about 1 gram of calcium oxide daily. Children of 6 to 7 years of age need 0.5 to 0.5 gram, and children of 14 should receive 0.6 to 0.9 gram daily.<sup>24</sup> Denis and Minot<sup>25</sup> found that calcium-poor diets and calcium-rich diets had little effect on the serum calcium. Matz<sup>15</sup> however found that a meal containing the equivalent of 0.917 gram of calcium oxide caused no rise in serum calcium but one containing 1.8 grams caused a rise of 1 mg. per 100 c.c.m. at the end of three hours after which it fell again and that three meals in a day containing 2.34 grams caused a rise during the day of from 1 to 2 mg. per 100 c.c.m. Matz further showed that the ingestion of cod liver oil and calcium lactate caused a greater rise than calcium lactate alone. Brauer and Ropes<sup>26</sup> studied the effect of doses of 5 grams and of 10 grams of calcium lactate by the mouth in normal subjects and found variable but definite rises in the serum calcium maximal in from one to four hours, and maintained, though diminishing, for twelve hours. The average maximal rise after 5 grams was 8 per cent above the normal, and after 10 grams 14 per cent. Jansen<sup>27</sup> found that when different calcium salts were given by the mouth in doses equivalent to 1.2 grams of Ca, a temporary rise of serum calcium was obtained with a maximum effect in two to three hours. He found the lactate to be without effect and the bicarbonate to give greater effects than the chloride. Hjort<sup>28</sup> obtained a constant rise in the serum calcium in normal dogs by the oral administration of amounts of the lactate chloride and glycerophosphate equivalent to 0.2727 gram of oxide per kilo but smaller doses of these salts and similar doses of less soluble salts were without constant effect.

It may be concluded, therefore, that the ingestion of calcium salts is able to raise the calcium content of the serum to an extent of less than 2 mg. per 100 c.c.m., but that the salts must be given in large doses of 5 to 10 grams to obtain this effect that such an effect is by no means constant and that it is maximal in about three hours and passes off in about twelve hours. Such an effect will have a therapeutic value in checking tetany when the calcium content of the serum is not excessively low, but the effect will be maintained only so long as the administration is continued. To obtain a permanent rise it will be necessary to administer parathyroid extract in addition in the case of post-operative tetany, and cod liver oil, or sunlight, or mercury vapour lamp irradiations in the case of the tetany accompanying rickets. It is not yet clear why oral administration of soluble calcium salts is without effect in some cases. Theoretical considerations point to the conditions of acidity and alkalinity of the digestive tract as likely to affect absorption and studies on this point would be of value. In the case of rickety infants the absence of vitamin D would appear likely to be the factor that interferes with absorption, even when sufficient calcium is being ingested.

If calcium should prove to be essential to the diuretic effects obtained with calcium chloride and to the effects on inflammatory exudates and local transudates then all these conditions could be treated by similar large doses administered orally.

**Intravenous**—The intravenous injection of 2 grams of calcium chloride dissolved in 50 c.c. or 100 c.c. of water can be utilized to raise the serum calcium promptly, and if given slowly no ill effects are produced. By this means the serum calcium can be raised 100 per cent, but the effect is transitory. This method is useful in controlling the severe manifestations of tetany, the convulsions, and laryngismus. Cameron<sup>4</sup> recommends the intramuscular injection of 1 gram of calcium chloride in infants with laryngismus.

**Indirect**—The indirect methods of influencing the calcium in the body are of perhaps greater practical importance than the direct administration of its salts. The influence on its absorption of cod-liver oil, mercury vapour lamp irradiations, sunlight, and the retention of the contents of the digestive tract have already been referred to. The recent work of Collip<sup>13</sup> on the parathyroid glands, and the elaboration by him of an extract that is constant in its action in normal dogs and capable of standardization, has opened up new methods of approach. This extract is prepared by Lilly and Company under the name of parathormone, and must be administered by injection. Stewart and Percival<sup>14</sup> find that it increases the ratio of diffusible to total calcium as well as raising the total serum calcium. Collip and others have studied its action in post-operative tetany, and Hunter and Aub<sup>22</sup> have reported its successful use in lead poisoning. Reports have been published of its use in one case of severe nephritis<sup>23</sup> and of its failure to influence definitely the course of pulmonary tuberculosis,<sup>24</sup> but there is no clear evidence as to its therapeutic value in these conditions. In spasmophilia, and in tetany accompanying rickets, it is theoretically contraindicated, except as an emergency.

I hope that this discussion will throw some light on the part that calcium plays in the effect of calcium chloride on oedema and on inflammatory exudates, that it will explain the inconstant effects of the oral administration, and that it will enlarge the field of calcium therapy. At present it appears that, apart from the actions of calcium chloride, which are possibly due to the chloride rather than the calcium, the field of usefulness is restricted to the treatment of tetany and deficient calcification of bone, and that even in these conditions other therapeutic measures are necessary in addition to obtain a satisfactory calcium effect. The uses of calcium salts in external applications, and of the less soluble calcium salts as antacids and astringents in dyspepsia, need no discussion.

## II—THE EFFECT OF CALCIUM IN CHILDREN

LEONARD G. PARSONS, M.D., F.R.C.P.,

Lecturer on Infant Hygiene and Diseases of Children, University of Birmingham

If the title of this discussion, "The therapeutic uses of calcium salts," means its limitation to a discussion of the role of calcium in those instances in which calcium salts are given medicinally, I have nothing to add to it, because my experience of these drugs is limited almost entirely

to their exhibition during the acute stages of infant tetany. I am therefore greatly relieved that the speaker has taken the wider view and has considered the variations in disease of the available calcium in the blood and how this can be increased in those instances in which it is lower than normal. With one modification I entirely agree with Professor Fraser's penultimate remark—for example, the field of usefulness of calcium salts is restricted to the treatment of tetany and deficient calcification of bone, and that even in these conditions other therapeutic measures are essential to obtain a satisfactory calcium effect. I do not think it is necessary to give calcium salts medicinally in order to produce calcification of bone, because if the diet of a young child be efficient it will contain sufficient calcium to supply the body requirements if only the absorption be normal. Thus estimations of the calcium in the diet in a series of 82 infants showed that the mean of calcium oxide intake varied from 2.36 to 0.43 grm, with an average of 1.129—a figure considerably in advance of that suggested by Professor Fraser as the normal calcium requirement. My remarks will be entirely confined to the problem of the calcium effect in children and the methods by which this can be produced. In dealing with the question of absorption of calcium I propose giving the results of some observations which may throw a certain amount of light on the cause of the inconstant effects of the oral administration of calcium salts.

Professor Fraser refers to the action of calcium chloride being possibly due to the chloride rather than to the calcium, a view strongly held by Gamble and his colleagues, and supported by the well known therapeutic fact that ammonium chloride—which also acts by virtue of its chlorine radicle—and hydrochloric acid will cause a temporary improvement in infantile tetany by producing a rise in the blood calcium. These drugs will also increase the blood calcium in low calcium rickets, but Ross and Seriver have shown that this result is due to a mobilization of calcium from the bones, and therefore the cure of rickets by this means is impossible. The most recent work on this subject is that by Drucker, who has shown that in therapeutic doses ammonium chloride usually causes an uncompensated acidosis, both in normal children and in those suffering from tetany, whereas calcium chloride usually gives rise to a compensated acidosis. Ammonium chloride, therefore, has the stronger acid effect on the blood, but, on the other hand, calcium chloride causes a larger rise in the amount of blood calcium when this is decreased, as in tetany. The effect of ammonium chloride in infantile tetany depends on an increase in calcium ions because the blood is rendered more acid, but that of calcium chloride is more lasting, and due chiefly to an increase in the number of calcium ions resulting from an increase in the previously low total calcium. It would therefore appear that the effect of calcium chloride in tetany is due both to the chloride and to the calcium.

It has also been pointed out by Professor Fraser that the calcium of the serum is partly diffusible and partly non-diffusible, that the diffusible calcium is the part for which the ionized fraction is derived, and that it is the latter which produces the specific calcium effects. If the calcium which produces the specific calcium effects is diminished tetany will occur. According to Drucker the calcium ion concentration in normal children, calculated on the Rona-Takahashi equation, is from 3.4 to 2.1 mg. per cent, with an average of 2.6 mg. per cent. The diffusible calcium, as estimated by the method of ultra-filtration through colloidal selenium, is at a negative pressure of 150 mm. of mercury, is about 50 to 60 per cent of the total calcium of the serum, but an attempt to estimate the diffusible calcium in my cases, using a pressure of this amount and filtration for four hours, has given figures almost identical with those given by Drucker for ion calcium, and previous to the publication of his results I had come to the conclusion that in tetany the ultra filtrate would be less than 2.5 mg. and usually under 2.2 mg. per cent.

Spasmophilic manifestations may, however, occur in certain circumstances with an undiminished blood calcium, indeed, some authorities have reported that the blood calcium when the blood calcium was higher than normal. But stenosis of infants furnishes some of the best examples of

the condition. Anyone who is familiar with this disease must have seen cases in which convulsions have occurred and recurred and eventually proved fatal, or in which—particularly shortly after the Rammstedt operation—the child showed periods of apnoea and arrested breathing followed by a period during which deeper breathing occurred and convulsions appeared, and after several such attacks the child was succumbed. This condition is one of all also is resulting from repeated vomiting and high intestinal obstruction with the consequent loss of chlorine ions. As a result of this alkalosis although the calcium in the serum is normal or higher than normal the ionic calcium is diminished. On the other hand in severe azotemic nephritis in which the serum calcium may be low, tetany may not occur because there is present an acidosis, which results in more of the calcium being ionized.

The therapeutic problem, therefore, becomes chiefly one of maintaining the ionic calcium at such a level (in small children over 2.2 mg. per cent.) that the specific effects of low calcium do not occur. Before considering how this can be accomplished I would like to refer to one or two other points in connection with calcium concentration in nephritis and in coeliac disease. Professor Fraser has referred to the diminution of serum calcium in severe azotemic nephritis and accepted the view that this is the result of phosphate retention. Experimentally the injection of phosphates into animal and children has been found to produce this effect, and also to produce tetany. Professor Fraser has suggested the possibility of administering calcium to lower the absorption of phosphate, but I doubt whether this would have any effect because of the inability of this type of kidney properly to secrete phosphate. In renal infantilism—that is, infantilism associated with severe chronic interstitial nephritis—although the blood calcium is relatively low when compared with phosphorus yet not infrequently a combination of high blood phosphorus with a normal or even higher than normal blood calcium is found. Such a combination however is associated with severe bone change—the so-called renal rickets. It would appear therefore, that any attempt to maintain a high blood calcium in adults suffering from severe azotemic nephritis by such methods as the administration of parathyroid hormone would produce an osteoporosis. It is true that tetany may not occur in severe azotemic nephritis because of the presence of an acidosis favouring increased ionization of the calcium, but young children are apparently more sensitive than adults to diminution in ionic calcium, and probably therefore to prevent tetany they raise their serum calcium to a higher level than the adult by drawing on their calcium reservoirs. They do not always seem to do this, however, with the result that tetany is not an uncommon complication of this form of nephritis as a temporary method of curing tetany in such cases parathyroid hormone might be helpful, but I have not had any personal experience of its use.

In coeliac disease the serum calcium and ionic calcium are low as also is the serum phosphorus. If the disease be severe and of long duration rickets and tetany occur as complications and can be cured by methods that increase the absorption of calcium and phosphorus.

Now what are the factors concerned in the absorption of calcium from the alimentary tract, and how can absorption be increased?

It has been shown that while excessive amounts of calcium in the diet tend to increase the total absorption and retention of calcium yet they impair phosphorus retention and vice versa and that the retention of one element in the intestine by an excessive amount of the other is best explained by the formation of insoluble phosphate of calcium. To obtain the maximum absorption of both elements—a necessary desideratum in infants and young children—the diet should contain amounts of calcium and phosphorus sufficient in quantity and properly balanced. The percentage of calcium in the diet should be greater than the percentage of phosphorus. In children one pint of milk daily will meet both these requirements.

Another factor in the absorption and retention of calcium is the presence of fat in the dietary and its normal absorption from the intestine. The presence of large quantities of unabsorbed fat in the intestine may lead to a negative calcium balance, thus in a case of infantile biliary cirrhosis,

in which owing to the exclusion of bile from the intestine, fat absorption was poor, a negative calcium balance was found, and in coeliac disease, a condition in which the fat absorption is very defective, a negative or low calcium retention is found. In precisely the same way a child fed on a low fat dietary may show a negative calcium balance. Thus an infant who ate diet—a milk mixture containing 2 per cent of fat—contained 0.44 gram of calcium oxide a day showed a percentage absorption of 34, but when fed on a mixture containing 0.8 per cent of fat for seventeen days showed a negative calcium balance, although the daily calcium intake was more than twice as much as in the previous diet. We have found that in infants showing a normal fat absorption the fat intake must be from 2 to 10 grams per kilo of body weight to ensure the absorption of 0.1 gram of calcium oxide per kilo of body weight. This effect of fat on the absorption of calcium is due to the presence of the fat-soluble vitamin D.

Telfer has produced evidence showing that the absorption of calcium only occurs in the upper part of the intestinal tract. The solution of the calcium salts in the food is affected by the acid of the gastric juice, and absorption proceeds until the acid mixture of lime and phosphoric acid is rendered alkaline by the intestinal secretions when calcium phosphate is precipitated in insoluble form. It has therefore been suggested that an increased acidity in the upper part of the intestinal canal would increase the absorption of calcium. Such is however not entirely borne out by my observations, thus in the case of biliary cirrhosis already quoted in spite of the presence of large amounts of free acid in the bowel the calcium balance was a negative one, and in another example of this condition the calcium absorption was very small although incidentally in both cases the absorption of phosphorus was greatly increased.

Observations have also been carried out in a number of atrophic infants fed on varying diets, some being fed on acid milk. The average calcium absorption of fourteen infants fed on lactic acid milk was considerably less than in a group of thirty-one infants fed on ordinary cow's milk mixture. This may in part be due to the fact that children fed on lactic acid milk excrete more fat than those fed on the ordinary mixtures. Four children fed on hydrochloric acid milk (that is, milk prepared by adding 1 oz. of decinormal hydrochloric acid to 4 oz. of milk) however showed a higher absorption of calcium, and although there was a marked increase in the amount of calcium excreted in the urine the actual calcium retention was definitely higher than in children fed on cow's milk. On the other hand Wills, Sanderson and Paterson found that in two children a positive calcium balance on cow's milk dietary was converted into a negative one by changing their diet to hydrochloric acid milk. Finally a group of six infants fed on almara, a food which has a buffer value similar to that of breast milk, showed the highest calcium absorption of all the children examined.

Zucker and Matzner found that rats kept on a high calcium low phosphorus rickets-producing dietary developed marked rickets alkalinity. It has been shown by Jephcott and Bacharach that in such animals the faecal pH can be reduced to the acid side of neutrality by means of cod-liver oil irradiated cholesterol or irradiation, and that the alkalinity can be prevented by irradiation. Indeed, they have recommended this change in pH as a test for the presence of vitamin D. It would appear then that it is not the increased acidity *per se* which is so important in the absorption of calcium as the occurrence of vitamin D, which by its presence leads to increased acidity in the intestinal tract.

The absorption of calcium from the intestinal tract is increased by giving by the mouth substances rich in vitamin D, such as cod-liver oil irradiated cholesterol irradiated ergosterol or by exposure to sunlight and ultra-violet irradiation.

The problem of how to increase calcium absorption in coeliac disease is complicated by the difficulty in absorption of fats in this disorder and because for its efficient treatment it is necessary to give a very low fat dietary for a long period of time. Actually when the fat in the diet is kept very low indeed the percentage absorption is

the second lobe was removed later. She went back to South Africa by herself. She now camps out, rides on horseback, and manages her household affairs.

One further aspect remains to be spoken of—namely, mental disorder. This complication is not common, but, taking a large number of cases, it is not infrequent. Some patients have suddenly become maniacal and died. I have had to decide what course to follow in patients who were gradually getting worse and who were approaching, or had reached, a stage when they could not be managed in their own homes. I have never operated upon these patients without the fullest consultation, and without the relatives appreciating all that is at stake, and sometimes a patient is too ill to justify operation. It is wise to have the help of a specialist in mental disorders before a decision is arrived at. Only one of these patients has not improved, the others have, after operation, returned to their ordinary way of living. One of them has married since, and one of the worst was driving her own car round London within eight weeks of her second operation.

The degree of recovery in these cases, and in the majority of cases, appears to be very high, and yet I think we must believe that in Graves's disease the secretion is not normal secretion, and when we reduce its amount by four-fifths we are not leaving a patient with an output of secretion normal in amount and quality, and therefore the end-results are not strictly comparable with those obtained after removal of a diseased appendix.

**Anorexia, with Emaciation.**—Now the other side of the picture. I have had three patients who have suffered from extreme anorexia—an unusual symptom in Graves's disease—associated with great wasting. The emaciation, as you know, is frequent, the anorexia is not, and I cannot help thinking that some factor with which we are not familiar is present. Of these three, one recovered after operation, one is just about holding her own, and one died some months subsequently.

Patients who have suffered severely from exophthalmic goitre never become normal as they were before the disease occurred, but they are a great deal nearer normal than if they had not been operated upon, and almost all of them can take up their work and enjoy life in the world once more.

I would ask you to bear in mind two points. We must visualize a heart and nervous system flooded with toxic secretion, sometimes continued for years. If that toxic secretion is suddenly reduced by four-fifths, the organs quickly show relief—often, indeed, dramatically—but it is unreasonable to expect that their complete recovery (their capacity to stand up to strain) should be other than gradual, and may never be quite complete. My second point is, that as soon as a sufficient operation is performed the patient feels a different woman, and is on an up grade all the time. She is conscious of this herself, and it is obvious to her friends.

## II—INDICATIONS FOR SURGICAL TREATMENT IN TOXIC GOITRE

BY

GEORGE R. MURRAY, D.L., M.D., D.C.L., F.R.C.P.,  
Emeritus Professor of Medicine in the University of Manchester,  
Consulting Physician to the Royal Victoria Infirmary, Newcastle,  
and to the Manchester Royal Infirmary.

It is important to regard the surgical treatment of toxic goitre from three points of view. When the question of an operation is under consideration it is advisable to take the opinion of the physician, the surgeon, and of the anaesthetist, if possible in consultation, in deciding whether medical treatment should be given. "Toxic goitre" treatment be adopted forthwith. The term "toxic goitre" includes all forms of goitre which give rise to general symptoms, as distinct from those in the neighbouring structures. These general or toxic symptoms are due either to

hyperthyroidism or to dysthyroidism—in other words they are the result of the passage from the goitre into the blood either of an excessive amount of normal thyroid secretion or of an altered secretion.

As the relative importance of changes in the quantity, as compared with those in the quality of thyroid secretion in the production of thyrotoxicosis is still open to discussion, the term "hyperthyroidism" will be used simply to indicate overactivity of thyroid secretion in whatever form it may ultimately be proved to occur.

In considering the indications for surgical treatment in this group of maladies we require some form of classification. Mr. Dunhill has given us a valuable lead in this respect from the surgical aspect. I find that rather a different arrangement is more convenient from the medical point of view, as the physician sees only and mild toxic of toxic goitre, in which the question of operation does not arise. A physician is apt to feel that all cases of toxic goitre ought to be amenable to medical treatment—indeed, we hope in the future they will be—and so is liable to look upon the necessity for surgical treatment as a confession of failure. There are, however, certain forms and stages of toxic goitre in which an operation at present affords the only means of cure or relief of the malady.

## CLASSIFICATION

I find the following classification is useful for practical purposes, but it must be clearly understood that there is no sharp line dividing the different groups, as intermediate cases occur.

In the first place it is advisable to divide all forms of toxic goitre into (a) primary, and (b) secondary groups. In the primary group may be placed all cases in which the onset of the toxic symptoms either precedes or coincides with the appearance of the goitre. In the secondary group the toxic symptoms only develop after a goitre of one kind or another, has been present for several years without causing ill health. It is in this secondary group that surgical treatment is most frequently required. There are two forms of primary toxic goitre: (1) simple hyperthyroidism (thyrotoxicosis), (2) exophthalmic goitre. There are three forms of secondary toxic goitre, which may be conveniently called: (3) simple secondary hyperthyroidism (thyrotoxicosis), (4) toxic adenoma, (5) secondary exophthalmic goitre. I shall now endeavour to describe briefly these five forms of toxic goitre, with special reference to the indications for surgical treatment in each of them. Brief details of a few cases will be given as examples.

## PRIMARY TOXIC GOITRE

## 1. Simple Primary Hyperthyroidism or Thyrotoxicosis

In this condition the thyroid gland is enlarged to slight or moderate degree. In some rare cases the toxic symptoms precede any palpable enlargement of the gland. The pulse rate at rest is increased to 90, 100, or more, and is easily accelerated by exertion or emotion. The mind is alert, and the hands tremble when extended. The skin is warm and moist, there is loss of weight, and gastric and intestinal symptoms may be present. The basal metabolic rate may be increased by as much as 50 per cent. The form of toxic goitre corresponds to the "formes frustes" of the French writers, and may be illustrated by the following case.

Miss R., aged 26, complains of palpitation on exertion and with occasional vomiting, perspiration, and nervousness. There is a uniform goitre of moderate size but no pressure. Pulse 100 to 104, no cardiac murmur, fine tremor, no exophthalmos. Medical treatment advised.

These patients are not seriously ill, they are not amenable to medical treatment, and so are referred to a surgeon. Occasionally a patient gets progressively worse, the pulse rate increases to 120 or more, the goitre enlarges and may begin to fibrillate, there is great weight loss, and severe gastro-intestinal symptoms are superadded. In these circumstances, even when the thyroid is not even palpably enlarged, an operation should be carried out without delay. It is not sufficient to say that serious thyrotoxicosis may occur and cure itself, while external examination fails to reveal any enlargement.

of the gland, the true nature of the malady only being revealed by the microscopical examination of the gland after death.

## 2 Primary Exophthalmic Goitre

In mild and moderately severe exophthalmic goitre medical treatment alone suffices in the majority of cases and should be given a fair trial for at least six months before it is abandoned in favour of an operation.

In a series of cases of exophthalmic goitre of all grades of severity under my care at the Manchester Royal Infirmary a thyroidectomy was performed in one-twelfth, as medical treatment had failed. In a few cases owing to the urgent necessity of earning a living or of removing some remote part of the world an immediate operation has been advised which in other circumstances would have been postponed. In some cases this course has proved successful in every way but there is a greater risk of death, which might have been averted if time and circumstances had allowed for prolonged medical treatment.

In a large majority of cases of Graves's disease the enlargement of the thyroid is only slight or moderate, and there are no pressure signs. In a few cases, however, the goitre is larger than usual. In these medical treatment is apt to fail so that even if pressure signs are entirely absent an early and extensive thyroidectomy is advisable. In all cases in which no decided improvement has taken place during six months of medical treatment the advisability of surgical treatment should be fully considered. In the physician and surgeon in co-operation. In selecting a surgeon it must be realized that special experience and capacity are just as important in a thyroidectomy as in a parathyroidectomy or in any larvageal operation.

One of the chief dangers to life in prolonged cases of exophthalmic goitre is due to the development of thyrotoxic myocarditis so that in cases in which medical treatment fails to prevent the onset of early signs of cardiac failure an operation should not be delayed. In the past an operation has frequently been considered too hazardous an enterprise to be undertaken in these cases but thanks to the work of Professor Frazer and Mr. Dunhill, we now know that signs of myocardial failure, such as auricular fibrillation and oedema of the legs are not a bar to operation but rather an indication that it should be carried out as soon as the patient has been prepared by medical treatment so as to minimize the risk of it as far as possible. In the case, as in all forms of thyrotoxic myocarditis it is important to realize the danger of delay as it is not fair to the surgeon to wait until the signs of cardiac failure are advanced before asking him to see the case with a view to operation.

Briefly the advantages of operation in primary Graves's disease are: (1) The saving of time owing to the prompt reduction of the thyrotoxicosis and immediate relief of symptoms. (2) The complete recovery in some cases and marked improvement in others. (3) The diminution of the risk of the development of chronic myocarditis.

The disadvantages are: (1) The risk to life. (2) The uncertainty of the ultimate result of the operation owing to the difficulty in determining the right amount of the gland which should be removed in each case. (3) The tendency to recurrence within a year or two with the necessity for further medical or surgical treatment.

The following case illustrates recovery after operation.

Miss M. aged 27 seen February 14th 1921. Eighteen months duration. Physical signs: Moderate uniform goitre; pulse 150 enlarged heart; exophthalmos; tremors. As this patient was very anxious to accompany her husband who was going to live in China at an altitude of some 7000 feet above sea level and was about to visit relatives in Minnesota I advised her to go to the Mayo Clinic for an operation. In the following June Dr. V. C. Hunt ligatured both the thyroid arteries. This was followed in September or a double lobectomy of the gland with removal of the isthmus. She was able to proceed to Japan in November and the first report received from her there stated that she was perfectly well.

The following case illustrates the tendency to recurrence after operation.

Miss L. A. a severe case of primary exophthalmic goitre in which the symptoms had developed acutely after a trying visit to a dental surgeon. First and medical treatment failed to relieve her. On two occasions a partial thyroidectomy was carried out by Sir Victor Horsley with benefit but when I saw her again

after an interval of ten years the symptoms were still well marked. They then subsided under x-ray treatment.

Mr. E. B. aged 41. Symptoms of exophthalmic goitre first developed in 1923. In 1914 a partial thyroidectomy was performed by Mr. Kelly of Liverpool. Improvement followed so that he was able to follow his occupation for the next ten years. When seen for the first time in 1925 the right lobe of the thyroid was absent and the left lobe had increased in size during the previous twelve months. Pulse 140 to 160 with marked exophthalmos; tremors; pigmentation of the skin; glycosuria.

## SECONDARY TOXIC GOITRE

### 3 Secondary Simple Hyperthyroidism or Thyrotoxicosis

In this group may be placed cases in which a simple colloid or parenchymatous goitre of several years' duration becomes toxic. This complication may arise, either gradually or rapidly, as a result of some emotional strain or for no apparent reason, long after the goitre first appeared. The symptoms are the same as in the primary form. The following are illustrative cases.

Miss P. aged 33 teacher. Duration of goitre long but uncertain as the neck had always been full. A definite swelling had appeared during the last month. For a year he had found her work too hard for her. She had vomited several times and had lost weight. Physical signs: Moderate uniform goitre with thrill and bruit; pulse 120; heart apex beat in left nipple line; systolic murmur at apex and over pulmonary area; slight ectatic widening of palpebral fissures and pigmentation of eyelids but no exophthalmos. Medical treatment advised.

Miss R. aged 35 teacher. Seen June 1st 1927. A goitre had been present for at least twenty-three years. She had recently lost her father, mother and brother. Six months ago she suffered from erythema nodosum. For the last five months he had had palpitation and tremors with sickness and diarrhoea at times. Physical signs: There is a uniform soft goitre of moderate size; the circumference of the neck being 16 in. pulse 140; systolic blood pressure 150 mm. diastolic blood pressure 100 mm. tremors moist skin and some loss of hair; increased frequency of defaecation; menses irregular. Medical treatment advised.

In these cases medical treatment may in the absence of urgent symptoms, be given a fair trial. The results are not so good as in primary hyperthyroidism, but the toxic symptoms may subside, although the goitre will persist even if it is reduced in size. If there are no marked results from medical treatment in three months a thyroidectomy should be advised.

### 4 Toxic Adenoma

The term "toxic adenoma" has been used with a varying significance by different authors. Some include the group which I have just described but it seems best to restrict the name to those cases in which a nodular goitre—that is to say, an adenomatous or adenoparenchymatous goitre which may be cystic—has been present for some time even many years before the toxic symptoms appeared. The cardiovascular symptoms are often prominent in these cases though wasting nervousness, tremors and gastro-intestinal symptoms may also be severe. The following are records of cases in this group.

Miss H. aged 41 seen January 3rd 1926. A goitre had been present for eight years. She had not been well since an attack of diphtheria after which she lost 2 st in weight. The right lobe of the thyroid was moderately enlarged and firm in consistency but there were no pressure signs. Pulse 124; systolic blood pressure 105 mm. heart apex beat in left nipple line. Nervousness and tremors were present but there were no eye signs. Menses regular. At operation on February 2nd 1926 Mr. Burges removed a large deeply buried adenoma of the right lobe. On examination by Dr. Lovdahl this showed the structure of a fibro-adenomatous goitre. In one part there was an atrophic condition with fibrosis and haemorrhage and in others marked adenomatous proliferation of the acini and some mucoid degeneration. Here and there an acinus was seen with columnar cell formation. On June 15th 1927 Dr. Leather reported that the patient was very well. When last examined early in the year the pulse was 70 to 80 never exceeding the latter; he was much less nervous and there were no tremors. She had gained 2 st in weight and the hair had begun to grow again.

Mr. H. aged 40 seen February 11th 1926. There probably had been some enlargement of the thyroid gland in childhood but during the last five years the left lobe had been definitely enlarged. For several years she had felt tired by mid-day. She had suffered from bronchitis and had been worried by her business. Recently she had a course of treatment during which she took one particle of Crookes's colloidal iodine 1 per cent. thrice daily and she had three doses of x-ray. On late she had lost weight the pulse frequency had increased and tremors were present. There was a uniform goitre with a small central adenoma. There were no pressure signs or eye signs. Pulse 130 to 140 irregular owing to auricular fibrillation; heart apex beat in left nipple line. Defaecation four or five times a day. Operation was advised after a preliminary course of digitalis. About

a fortnight later the left lobe and isthmus of the thyroid were removed by Dr. Craig of Kendal, ether being given by the rectum. The patient made an excellent recovery, and Dr. Craig recently informed me that she had gained 5 st in weight, the pulse was regular and not more than 88 even after a hard day at business. The tremors and nervous symptoms had entirely disappeared. She still finds that she cannot hurry or climb hills without some dyspnoea, but this is the only symptom left of the severe thyrotoxic myocarditis which was present when I saw her before the operation.

In the following case medical treatment was adopted, as the patient had a young family, and did not wish to run the risk of an operation.

Mrs. X had had a goitre for fourteen years. She complained of feeling tired at times of loss of weight, throbbing in the neck, and of palpitation, especially during the last three months. There was a moderate uniform enlargement of both lobes of the thyroid with a small central adenoma the size of a cherry. Pulse 120, heart apex beat in left nipple line. Tremors were present.

In cases of true toxic adenoma operative treatment is advisable as soon as the symptoms become moderately severe, as medical treatment is of little permanent value. In a few cases in which operation has been declined or postponed and medical treatment has been continued some diminution of the toxic symptoms has followed x-ray and medicinal treatment, although there has been no diminution in the size of the goitre, but such improvement is apt to be of short duration.

### 5 Secondary Exophthalmic Goitre

A convenient group is formed by all the cases in which the goitre has been present for several years before the onset of Graves's disease. In order to give further subdivision these cases may be grouped together whatever the character of the pre-existing goitre. In these cases exophthalmos and the other characteristic symptoms of Graves's disease are present. Secondary exophthalmic goitre is not common in this country; in a series of 300 cases seen by me in private practice only twelve were secondary. It is not so amenable to medical treatment as the primary form of the malady. In the majority of the cases, especially when the goitre is either large or nodular, an operation should be advised as soon as the symptoms are well marked. If this cannot be carried out medical treatment must perforce be continued, but the results are disappointing and myocardial changes are only too prone to progress to complete myxedema or to a fatal termination.

Mrs. H., aged 57, first noticed that she had a goitre twenty years ago, this diminished in size after the application of iodine paint. Three years ago she began to feel tired and suffered from palpitation and insomnia. The weight decreased from 9 st 3 lb to 7 st. There was a cystic and nodular goitre. Pulse 140, slightly irregular, blood pressure 160/100, heart apex beat heaving, external to nipple line, left lobe murmurs, slight exophthalmos, tremors. A suitable case for operation.

There is one special form of goitre in which, though it is truly toxic, the symptoms are not due to hyperthyroidism. I refer to the septic goitre in which an adenoma or cyst becomes infected and gives rise to a general toxæmia. I have recorded such a case in which infection of an old cystic goitre by *Ale. colon bacillus* caused an intense toxæmia, which promptly subsided when the pus and gas were removed. The treatment of these cases is purely surgical.

There is no doubt that in some cases of toxic goitre focal sepsis plays a part in starting or in aggravating the thyrotoxicosis, either by way of a subinfection or a toxæmia. In my own experience the frequency and importance of focal sepsis has not been nearly so great as has been stated by some writers. In every case, however, a careful search must be made, and if a septic focus is found it must be dealt with by surgical means appropriate to its situation.

The type of operation and the choice of the anæsthetic must, of course, be left to the discretion of the surgeon and the anæsthetist. When surgical treatment has been selected the physician wishes as much of the abnormal gland to be removed as will ensure early improvement and, if possible, cure without recurrence, enough of the gland being left to prevent the onset of post-operative myxedema. It is thus no light task we ask the surgeon to perform, but when the ideal result is obtained we are all the more

grateful for what he has done for our patient. From the medical point of view a subtotal thyroidectomy, in which seven-eighths of the goitre are removed at once, appears to be the most desirable procedure in the majority of cases. After the modern methods of preparation of the patient in which medical treatment plays such an important part, preliminary ligation of the thyroid arteries and piecemeal operations should seldom be necessary. Finally it must be remembered that, in some cases, although marked improvement follows the operation, the patient is still far from being well and may still require medical treatment for a considerable period before recovery takes place.

### Discussion

Mr. C. THURSTON HOLLAND (Liverpool) related the case of a deeply grounded, wasted, vomiting woman, to whom operation had been refused by a surgeon, x-rays cured her. He believed many patients treated by surgery could have been benefited by x-rays. They should always be used in early cases, and in advanced cases astonishing results occurred. The mortality was nil. Trix burns and telangiectases should never be caused. He did not think myxœdema resulted from the use of x-rays.

Professor R. E. KELLY (Liverpool) pleaded for intratracheal anæsthesia. An x-ray photograph, to show the position of the trachea, was useful. Warming the ether vapour was unnecessary, though moistening was advantageous. Toxic adenomatous patients were very susceptible to morphine. Iodine should be given for one week before operation upon true exophthalmic goitre. Though the early case with symmetrical enlargement was much improved by iodine administration, the patient with adenoma and hyperthyroidism did not respond to anything like the same extent.

Dr. JOHN EASON (Edinburgh) stressed the importance of primary exophthalmic goitre. Death, in the vast majority of cases, was remote. Early operation restored a patient to normal function and stopped the deterioration of important organs. He thought operation probably raised the general death rate, when, however, deterioration of important organs had set in, operation should be considered. He desired evidence of early operative mortality. Most young people with exophthalmic goitre adjusted themselves to ordinary life activities. He regarded the general policy of operation as wrong, to justify surgical intervention the risk of deterioration must be obvious or medical treatment be unobtainable.

Sir W. DE COURCY WIFFLER (Dublin) said that in estimating the effects of various treatments it was necessary to remember that the disease was one of cycles, normal improvement during one of the cycles could be hastened by x-rays and the administration of iodine. Recurrence of crises, he believed, could only be certainly prevented by a thorough surgical operation. Of 80 patients, all of whom were definitely toxic, every one had had medical treatment with or without x-rays, for months or years before seeking surgical help because the cures were of a transitory nature. Iodine was very potent generally in bringing about temporary improvement. He thought that the cure of adenomatous goitres of women were made toxic by the administration of iodine, and the effect upon the cardiovascular system was often disastrous. The effect of iodine in true goitres was admirable and dramatic in about half the cases. In about one-third some improvement was noticed and in the rest there was no obvious effect. He had seen a patient with Graves's disease become very much improved with iodine. The mortality of operation in early cases was almost nil. He employed rectal anæsthesia combined with a local anæsthetic, a few patients had had general anæsthesia only.

Mr. JOHN MORLEY (Manchester) said that surgery and x-rays alone had no effect upon true primary toxic goitre, the former brought about a much more rapid improvement than x-ray treatment. The mortality had been lowered very much of late years, and Lugol's solution

had helped a great deal. The operation should be performed seven to fourteen days after the institution of iodine therapy, seven eighths of the gland should be removed. Preliminary ligaturing of the arteries had not proved satisfactory and therefore the whole operation should be performed at one sitting. A ray was apt to leave cardiac disturbance unaffected.

Mr A. I. WALTON (London) stated that advanced colloid goitre, if it persisted to middle life changed to diffuse adenomatous goitre. This kind of goitre rarely gave rise to exophthalmic symptoms. The exophthalmic goitre was vascular in type in young people and nervous in type in older women about the menopause. Operation often failed to relieve this second group. He believed the medical mortality to be pretty considerable. A ray had no effect at all upon the disease in his experience though they performed wonders in carcinoma of the thyroid. He had never seen fibrosis of the thyroid after exposure to x rays. Lugol's solution was excellent as a preliminary drug.

Dr L. A. ROWDEN (Leeds) said that in twenty years only seven cases of toxic goitre had been operated upon at Leeds. All the other cases had been referred to the radiographer as the surgeons in this town regarded x ray treatment as the method of choice. If the full effect were to be obtained by this means it was necessary to give such doses that the skin was bound to be damaged. He had had experience of 550 patients. Severe cases recent cases, cases with high basal metabolic rate and cases with small glands did best. He strongly advocated x ray treatment.

Dr F. N. C. STARR (Toronto) said that he had consulted his records for 1926, and with his assistants he had continued during that year 253 benign cases often according to Mr Holland. He had given up advising x rays or radium treatment, which did no good in the adenomas whether hyperplastic or simple and was dangerous in the diffuse hyperplasia. In ten cases treated some years previously the two latest patients had succumbed within a few hours after the first x ray treatment. With really ill patients the cure was so long delayed that it was not worth while subjecting them to the misery of six months' to a year's treatment when a few weeks would accomplish what x rays failed to do. Dr Starr thought that the goitre problem was changing at least on his side of the Atlantic. Twenty years ago in Toronto there were many non-toxic cases and an occasional case of Graves' disease. Now however the tables were turned. Last year out of 253 cases operated upon 27 only were non-toxic, and 10 were of the diffuse colloid type with hyperplasia, or pre-ent colloid adenoma with a small amount of diffuse hyperplasia. 52 were definite hyperplastic adenomas while 119 were diffuse hyperplasia. Finally, 54 cases which so far as he knew, seemed to be local were of the diffuse hyperplastic goitre variety with hyperplastic adenomas as well. These latter always aroused great concern, but after operation the result was spectacular, provided that judgement did not fail and an operation was performed at the psychological moment. A preliminary rest treatment in the hospital was greatly to be preferred to rest at home because often the entire cure was lost by the journey to the hospital. In addition a minimum of two quarts of water together with overfeeding and the use of Lugol's solution hastened the improvement. Often when a patient was apprehensive if she could be placed in a two-bed room or in a large ward next to a patient who was convalescing after a very serious illness she would improve more rapidly as the patient who was recovering talked about the great benefits obtained.

Mr C. H. JOEL (London) said there were many patients with adenomatous glands and only slight toxic symptoms and this had been included in many statistics so that confusion had resulted. True exophthalmic goitre showed severe metabolic and nervous disturbances. Symptoms rose and fell in severity in a highly variable and apparently capricious fashion. In the toxic adenoma they were constantly progressive and involved the cardio-vascular apparatus far more than any other systems. He had

never seen true exophthalmos in toxic adenomatous case. Iodine had a good effect on both groups. Surgery was indicated in most patients arising from exophthalmic goitre, but shrewd judgement was required in deciding how much gland to remove, and this was often taken away. In toxic adenoma less need be removed. The mortality was less in toxic adenomas than in exophthalmic goitre. He had treated 57 per cent of his own cases and in general the results were good.

Mr DENNIS in reply said that surgical opinion was gradually becoming crystallized as to the place surgery should take in the treatment of toxic goitre. He did not advocate operation in early cases.

## THE THERAPEUTIC USES OF CALCIUM SALTS

### I.—THE PART PLAYED BY CALCIUM IN THE LIVING ORGANISM\*

—BY

FRANCIS P. TRASEP, M.D., F.R.C.P.

Professor of Medicine, St. Bartholomew's Hospital,  
University of London

AN understanding of the indications for the administration of calcium in the treatment of disease and of diseased persons is complicated by the fact that this substance is always present in the body. Further it is present in the blood in amounts that are remarkably constant. The serum in health contains about 10 mg. per 100 c.c.m. Variations of from 9 to 12 mg. have been recorded by various workers, but some investigators obtain more constant figures. A serum content so constant as this points to the presence of some mechanism that maintains a balance between absorption and elimination and deposition which must be taken into account in rational calcium therapy. Further this constancy in the calcium content of the serum in health suggests that it plays an important part in the life of the individual and the relation of the body to its environment.

The source of the body calcium is the calcium in the food ingested. Only a small proportion of the ingested calcium is absorbed most of it being passed from the body in the faeces. The greater part of the absorbed calcium is excreted back into the digestive tract and eliminated with the faeces but a small fraction is eliminated in the urine. During childhood considerably more is absorbed than is eliminated since much is retained for the proper construction of the bony skeleton.

Our knowledge of the functions of calcium in the living organism is vague, and probably is scanty at present. Certain facts are however well established. It enters into the mechanism of the clotting of blood and is essential to this mechanism. A low content of calcium in the serum is associated with a disturbance of the neuromuscular apparatus so that the electrical excitability is increased and tetany may result. It appears to be essential to the proper contraction of heart muscle since the perfused heart ceases to beat sooner if calcium salts are absent from the perfusion fluid, and beating recommences on the addition to the fluid of a soluble calcium salt. It is an essential constituent of bone.

In addition to these specific functions it plays an important part in the balance of ions in the tissues and fluids of the body. Undoubtedly this ionic balance enters into all of these functional activities that have been specified and disturbances of this balance occur in the abnormal states in which these functions are impaired. It is probable that in many more functional derangements not yet elucidated, calcium plays a part through upsets in this balance of the ions. A balance between calcium and magnesium ions on the one hand and sodium and potassium ions on the other, has been demonstrated in normal

\* Opening paper of a discussion in the Section of Therapeutics and Pharmacology at the Annual Meeting of the British Medical Association at Edinburgh 1927. Professor J. A. Gunn presided.

life, and this balance may be disturbed by alterations in the ionic concentrations of any of these elements. The part played by calcium in spasmophilia and tetany, and in the contraction of heart muscle, must be viewed as exercised through this balance of ions as well as by calcium specifically. For example, calcium is essential to the normal functioning of the neuro-muscular apparatus, but increased electrical excitability may be produced either by a decrease in calcium or by an increase in sodium or potassium.

A balance also exists between the basic ions, such as sodium and calcium, and the acid ions, so that an increase in the acid radicals is accompanied by an increase in basic ions, the balance, upon which the hydrogen-ion concentration depends, being kept almost constant in health. Further, calcium exists in a solid form as  $\text{Ca}_3(\text{PO}_4)_2$  in bone, and a balance must exist between the  $\text{Ca}^{++}$  ions and the  $-\text{PO}_4^{---}$  ions and the solubility of the  $\text{Ca}_3(\text{PO}_4)_2$ , so that the product of ionic concentration cannot rise above a certain level. An increase in the product will cause a deposition of solid  $\text{Ca}_3(\text{PO}_4)_2$ , and a diminution will result in the passage of  $\text{Ca}_3(\text{PO}_4)_2$  from the deposits in the bones into solution in the body fluids. An increase in the concentration of  $\text{PO}_4^{---}$  ions will, however, result in a diminution of  $\text{Ca}^{++}$  ions, the product remaining constant.

These very superficial considerations must suffice to show that disturbances in the specific functions of calcium due to insufficiency are merely symptomatic of abnormalities that may be far-reaching in their consequences and remote in their causation, while any attempt to influence the specific functions by increasing the concentration of calcium above the normal may have effects on important constituents of the body and on remote functions.

#### Serum Calcium

The amount of total calcium in the serum is used as an indication of the calcium supply in the living body. All of this calcium, however, is not in the same condition of chemical combination. The quantity that is in an ionized state has been variously estimated as only 20 to 25 per cent of the total. The work of Salvesen and Linder<sup>8</sup> suggests that part is in combination with protein, and this part will not only be in an un-ionized form but in a non-diffusible form, and therefore not easily available for utilization by the tissues. The diffusible calcium is not easily estimated with accuracy, but from observations by many workers it would appear to constitute 50 to 60 per cent only of the total.<sup>9</sup> Since this diffusible calcium is alone available for producing specific or ionic calcium effects, it is obvious that figures for the total calcium of the serum may not give a true indication of the available calcium. From the work of Vines<sup>10</sup> it would appear that about 4 mg. of calcium per 100 ccm. that was in a non-diffusible form in the whole blood is converted into a diffusible form during the process of clotting. If this is confirmed the figure for the total serum calcium is still further from being a true indication of the available calcium. In considering the significance of departures from the normal values for the calcium content of the serum it is important to remember, therefore, that they may affect (a) the non-diffusible fraction combined with protein, (b) the diffusible and easily ionized fraction, or (c) the ionized fraction. It is possible also that even when normal values for the total calcium are obtained the available calcium may be present in deficient amounts. Until simple and accurate methods are devised for estimating the available calcium in the blood its therapeutic uses cannot be placed on a satisfactory basis.

#### Indications for Calcium Therapy

**Nephritis.**—The total calcium of the serum is definitely reduced in severe nephritis.<sup>11, 12, 13</sup> In the forms with pronounced oedema there is reduction also in the serum proteins, and Salvesen and Linder<sup>8</sup> suggest that the reduction in such cases affects mainly that fraction that is in combination with proteins. They showed<sup>8</sup> that the reduction in calcium and in proteins is not the result of simple dilution, but that there is a reduction in the total proteins of the plasma even after the disappearance of oedema. It is difficult to see how an increase in the serum

calcium, if it could be brought about directly, would of itself be of benefit in this form of nephritis, but a therapeutic measure that would diminish the oedema might well be of benefit to the patient, and might at the same time increase the calcium content of the serum. Blum<sup>14</sup> and his co-workers have advocated the administration of calcium chloride for this purpose, and in his paper and in those of many others it has proved to be an effective diuretic in many cases. It is certain, however, that its action is not due to a specific action of calcium and the restoration of the serum calcium to a higher level. It would appear that it acts by the change that it makes in the balance of ions in the body fluids. Blum maintains that by increasing the calcium ions the sodium ions are decreased, and since the retention of fluids is closely associated with the retention of sodium, the oedema is decreased. Another explanation, however, is possible. The administration of calcium chloride results in the setting free of  $\text{Cl}^-$  ions, the calcium being retained in or excreted into the intestines as carbonate. The  $\text{Cl}^-$  ions are thus able to cause an increased acidity, and, to correct for this, sodium is excreted as sodium chloride, accompanied by large amounts of water. This latter explanation is supported by the similar beneficial action of ammonium chloride or nitrate. It is, of course, conceivable that the administration of the calcium chloride has some effect from the calcium, as Blum maintains, in addition to its undoubted effect as an acid forming substance. In severe cases of azotemic nephritis the serum calcium is definitely reduced, and this is accompanied by an increase in the inorganic phosphorus of the serum. It seems probable, as de Wesselow<sup>15</sup> has pointed out, that the low calcium content is the result of retention of phosphates and the consequent disturbance in the ionic balance. If, as he suggests, the phosphate retention is directly responsible to some degree for the toxic state known as uraemia, there would be reason to administer calcium to lower the absorption of phosphates. As far as I am aware, no clearly beneficial results have been reported in this form of nephritis by the administration of calcium or by the adoption of any indirect method of raising the calcium content of the serum such as the administration of parathyroid extract.

**Tetany.**—In tetany, following the removal or extreme disturbance of the parathyroid glands during the operation or thyroidectomy, the serum calcium is definitely reduced. Tetany is strictly a symptom of a more fundamental disturbance, but is a crippling condition and one dangerous to life. In post-operative tetany it is specifically due to the low calcium content of the body fluids, and can be relieved by raising the calcium content. The recent work of Collip<sup>16</sup> has clearly demonstrated the importance of the parathyroid glands in maintaining the calcium at its normal level in the serum, and the administration of extracts of the parathyroid glands, besides being a rational treatment in post-operative tetany, is able to raise the calcium content of the serum and reduce the tetany. There is much evidence of an indirect nature in favour of the view that parathyroid extracts raise the serum calcium by mobilizing the calcium that is stored in the bone and tissues, and that their action does not depend upon the absorption of calcium from the digestive tract. Russell, Stewart and Percival<sup>17</sup> have reported experiments that seem to give direct proof of this. The oral administration of calcium salts in excess, however, can raise the level of calcium in the serum and may relieve tetany, and intravenous administration gives prompt but transient relief. In tetany and spasmophilia accompanying renal disease the calcium is low. The use of parathyroid extract in such cases is contraindicated, except as an emergency, as increased serum calcium is obtained by the release of calcium from the bones, which are already deficient in calcium. In this condition the low calcium would appear to be due to poor absorption, either because of low calcium diet or the absence of vitamin D. The low phosphorus content of the serum which is found in such cases is probably an important factor in the defective utilization of calcium. The less constant reduction in calcium in the serum in the case of calcium salts and cod liver oil will affect the calcium in the serum to a normal level, and the measures is exposure of the patient, or of the

food to sunlight or ultra-violet light may be all that is necessary for the proper treatment of the rickets and the relief of the spasmophilia.

**Skin Diseases.**—Low values for the serum calcium have been reported in various skin diseases such as lupus erythematosus<sup>1</sup> but there is no evidence that the deficiency of calcium is of significance in the pathology of the disease, and no clear evidence that raising the calcium level influences the course of the disease.

**Chronic Infections.**—In many and various diseases associated with chronic infections Grove and Vines<sup>15</sup> find that although the total calcium content of the serum is within physiological limits, the amount of active or diffusible calcium is reduced. They further considered that the oral administration of parathyroid extracts and soluble calcium salts was beneficial in these conditions by raising the ratio of active to total calcium. The methods employed by them in their calcium estimations are open to criticism, and the reports of the therapeutic results in their clinical investigations are not convincing. Confirmation of their results is necessary before the scope of calcium therapy can be accepted as embracing the conditions enumerated by them.

**Haemorrhage.**—The administration of calcium has been advocated in many conditions in which there is no evidence of calcium deficiency. The basis for such therapies may be the attempt to obtain an exaggeration of a specific calcium effect, or to correct a disturbed ionic balance. In 1896 Wright<sup>1</sup> advocated the use of calcium chloride administered by the mouth to reduce the prolonged coagulation time seen in haemophilia. Even when the coagulation time is not unduly prolonged, an increased serum calcium has been shown by Matz<sup>16</sup> and Cantarow, Caven, and Gordon<sup>17</sup> to be associated with a reduction in the coagulation time. Its use has been reported in many cases in which the coagulation time is prolonged, but also in others such as purpura and pulmonary tuberculosis in which no such prolongation is found but the results are very irregular and in view of the numerous factors present in patients and the numerous therapeutic procedures that are unavoidably employed at the same time it is difficult to accept the evidence available as proof of the value of internal calcium therapy to control bleeding. Walters<sup>8</sup> considers that the injections of calcium chloride in the preparation for operation of patients with jaundice has reduced the risk of bleeding. I have not yet seen the evidence on which his opinion is based but it is obvious that careful observations on coagulation time and bleeding time would be of great value, and that there is sufficient ground for the view that there may be a scope for calcium therapy in the control of haemorrhage.

**Myocardial Weakness.**—In 1922 Cheimisse<sup>1</sup> reported that his clinical studies suggested that calcium salts by the mouth enhanced the effects of digitalis making them more rapid in their appearance and enabling a greater beneficial effect to be obtained before the onset of toxic effects. In 1924 Billigheimer<sup>18</sup> found that in normal persons and in patients with heart failure, calcium chloride intravenously had an action very similar to that of digitalis, but that it was more fleeting. He considered that it acts on vagal nerve endings and on the inhibitory centres in the heart. It had no effect on the tachycardia that results from atropine, but checked the acceleration following the injection of adrenaline. There is not at present sufficient evidence for the use of calcium in the treatment of myocardial weakness in patients.

**Inflammatory and other Exudates.**—It has already been mentioned that French workers notably Blum, have pointed out the powerful diuretic action of calcium chloride in nephritic oedema. Blum has shown a similar action in cardiac oedema. That ammonium chloride acts in a similar manner suggests that it is the acid properties of these salts which are responsible for their action as a diuretic though the calcium may have an effect in the same direction by its antagonistic action to sodium. Blum<sup>19</sup> has extended his observations to inflammatory exudations, and has reported beneficial therapeutic effects in pleural and peritoneal effusions and in inflammation of the conjunctiva. It may be argued that the suppression of inflammatory reaction is not desirable,

except occasionally, when exudations have embarrassed mechanical effects, but Blum's arguments are based on chemical improvement and the disappearance of fever as well as on the absorption of exudates. Based presumably upon this action of calcium ions and of chloride ions on exudations and transudations beneficial results of the administration of calcium chloride have been reported in such conditions as oedema of the glottis,<sup>20</sup> asthma,<sup>21</sup> oedema of the lung,<sup>22</sup> angioneurotic oedema, urticaria, and Raynaud's disease. If convincing evidence can be brought forward that such beneficial actions are due to calcium an extensive and important addition will be made to the scope of calcium therapy.

#### Methods of Administration

**Oral.**—Most writers agree that oral administration of calcium salts is inconstant in its effects, and at best produces only a moderate rise in the level of the serum calcium in healthy subjects. The normal calcium requirement for a healthy adult has been variously estimated but the consensus of opinion places it at about 1 gram of calcium oxide daily. Children of 6 to 7 years of age need 0.3 to 0.5 gram, and children of 14 should require 0.6 to 0.9 gram daily.<sup>23</sup> Davis and Minot<sup>24</sup> found that calcium-poor diets and calcium rich diets had little effect on the serum calcium. Matz,<sup>16</sup> however, found that a meal containing the equivalent of 0.917 gram of calcium oxide caused no rise in serum calcium, but one containing 1.8 grams caused a rise of 1 mg per 100 c.c.m. at the end of three hours, after which it fell again and that three meals in a day containing 2.34 grams caused a rise during the day of from 1 to 2 mg per 100 c.c.m. Matz further showed that the ingestion of cod liver oil and calcium lactate caused a greater rise than calcium lactate alone. Brauer and Ropes<sup>25</sup> studied the effect of doses of 5 grams and of 10 grams of calcium lactate by the mouth in normal subjects, and found variable but definite rises in the serum calcium, maximal in from one to four hours, and maintained, though diminishing for twelve hours. The average maximal rise after 5 grams was 8 per cent above the normal and after 10 grams 14 per cent. Jansen<sup>26</sup> found that when different calcium salts were given by the mouth in doses equivalent to 12 grams of Ca a temporary rise of serum calcium was obtained with a maximum effect in two to three hours. He found the lactate to be without effect and the bicarbonate to give greater effects than the chloride. Hjort<sup>27</sup> obtained a constant rise in the serum calcium in normal dogs by the oral administration of amounts of the lactate, chloride, and glycerophosphate equivalent to 0.2727 gram of oxide per kilo but small doses of these salts and similar doses of less soluble salts were without constant effect.

It may be concluded, therefore, that the ingestion of calcium salts is able to raise the calcium content of the serum to an extent of less than 2 mg per 100 c.c.m., but that the salts must be given in large doses of 5 to 10 grams to obtain this effect, that such an effect is by no means constant and that it is maximal in about three hours and passes off in about twelve hours. Such an effect will have a therapeutic value in checking tetany when the calcium content of the serum is not excessively low, but the effect will be maintained only so long as the administration is continued. To obtain a permanent rise it will be necessary to administer parathyroid extract in addition in the case of post-operative tetany, and cod liver oil, or sunlight or mercury vapour lamp irradiations in the case of the tetany accompanying rickets. It is not yet clear why oral administration of soluble calcium salts is without effect in some cases. Theoretical considerations point to the conditions of acidity and alkalinity of the digestive tract as likely to affect absorption and studies on this point would be of value. In the case of rickets infants the absence of vitamin D would appear likely to be the factor that interferes with absorption, even when sufficient calcium is being ingested.

If calcium should prove to be essential to the diuretic effects obtained with calcium chloride, and to the effects on inflammatory exudates and local transudates then all these conditions could be treated by similar large doses administered orally.

**Intravenous**—The intravenous injection of 2 grams of calcium chloride dissolved in 50 c.c. or 100 c.c. of water can be utilized to raise the serum calcium promptly, and if given slowly no ill effects are produced. By this means the serum calcium can be raised 100 per cent, but the effect is transitory. This method is useful in controlling the severe manifestations of tetany, the convulsions, and laryngismus. Cameron<sup>1</sup> recommends the intramuscular injection of 1 gram of calcium chloride in infants with laryngismus.

**Indirect**—The indirect methods of influencing the calcium in the body are of perhaps greater practical importance than the direct administration of its salts. The influence on its absorption of cod-liver oil, mercury vapour lamp irradiations, sunlight, and the action of the contents of the digestive tract have already been referred to. The recent work of Collip<sup>13</sup> on the parathyroid glands, and the elaboration by him of an extract that is constant in its action in normal dogs and capable of standardization, has opened up new methods of approach. This extract is prepared by Lilly and Company under the name of parathormone, and must be administered by injection. Stewart and Percival<sup>14</sup> find that it increases the ratio of diffusible to total calcium as well as raising the total serum calcium. Collip and others have studied its action in post-operative tetany, and Hunter and Aub<sup>15</sup> have reported its successful use in lead poisoning. Reports have been published of its use in one case of severe nephritis<sup>12</sup> and of its failure to influence definitely the course of pulmonary tuberculosis,<sup>13</sup> but there is no clear evidence as to its therapeutic value in these conditions. In spasmophilia, and in tetany accompanying rickets, it is theoretically contraindicated, except as an emergency.

I hope that this discussion will throw some light on the part that calcium plays in the effect of calcium chloride on oedema and on inflammatory exudates, that it will explain the inconstant effects of the oral administration, and that it will enlarge the field of calcium therapy. At present it appears that, apart from the actions of calcium chloride, which are possibly due to the chloride rather than the calcium, the field of usefulness is restricted to the treatment of tetany and deficient calcification of bone, and that even in these conditions other therapeutic measures are necessary in addition to obtain a satisfactory calcium effect. The uses of calcium salts in external applications, and of the less soluble calcium salts as antacids and astringents in dyspepsia, need no discussion.

## II—THE EFFECT OF CALCIUM IN CHILDREN

LEONARD G. PARSONS, M.D., F.R.C.P.,  
Lecturer on Infant Hygiene and Diseases of Children, University of Birmingham

If the title of this discussion, "The therapeutic uses of calcium salts," means its limitation to a discussion of the role of calcium in those instances in which calcium salts are given medicinally, I have nothing to add to it, because my experience of these drugs is limited almost entirely

to their exhibition during the acute stages of infant tetany. I am therefore greatly relieved that the speaker has taken the wider view and has considered the variations in disease of the available calcium in the blood and how this can be increased in those instances in which it is lower than normal. With one modification I entirely agree with Professor Fraser's penultimate remark—for example, that the field of usefulness of calcium salts is restricted to the treatment of tetany and deficient calcification of bone, and that even in these conditions other therapeutic measures are essential to obtain a satisfactory calcium effect. I do not think it is necessary to give calcium salts medicinally in order to produce calcification of bone, because if the diet of a young child be efficient it will contain sufficient calcium to supply the body requirements if only the absorption be normal. Thus estimations of the calcium in the diet in a series of 82 infants showed that the amount of calcium oxide intake varied from 2.36 to 0.43 grams with an average of 1.129—a figure considerably in advance of that suggested by Professor Lissner as the normal calcium requirement. My remarks will be entirely confined to the problem of the calcium effect in children and the methods by which this can be produced. In dealing with the question of absorption of calcium I propose giving the results of some observations which may throw a certain amount of light on the cause of the inconstant effects of the oral administration of calcium salts.

Professor Fraser refers to the action of calcium chloride being possibly due to the chloride rather than to the calcium, a view strongly held by Gamble and his colleagues, and supported by the well known therapeutic fact that ammonium chloride—which also acts by virtue of its chloride radical—and hydrochloric acid will cause a temporary improvement in infantile tetany by producing a rise in the blood calcium. These drugs will also increase the blood calcium in low calcium rickets, but Ross and Sever have shown that this result is due to a mobilization of calcium from the bones, and therefore the cure of rickets by this means is impossible. The most recent work on this subject is that by Drucker, who has shown that in therapeutic doses ammonium chloride usually causes an uncompensated acidosis, both in normal children and in those suffering from tetany, whereas calcium chloride usually gives rise to a compensated acidosis. Ammonium chloride, therefore, has the stronger acid effect on the blood, but, on the other hand, calcium chloride causes a larger rise in the amount of blood calcium when this is decreased, as in tetany. The effect of ammonium chloride in infantile tetany depends on an increase in calcium ions in the blood is rendered more acid, but that of calcium chloride is more lasting, and due chiefly to an increase in the number of calcium ions resulting from an increase in the previously low total calcium. It would therefore appear that the effect of calcium chloride in tetany is due both to the chloride and to the calcium.

It has also been pointed out by Professor Lissner that the calcium of the serum is partly diffusible and partly non-diffusible, that the diffusible calcium is the part from which the ionized fraction is derived, and that it is this latter which produces the specific calcium effects. If the calcium is diminished tetany will occur. According to Drucker the calcium ion concentration in normal children, calculated on the Rona-Tillich equation, varies from 3.4 to 2.1 mg. per cent, with an average of 2.6 mg. per cent. The diffusible calcium as estimated by the method of ultrafiltration through colloidal membranes under a negative pressure of 150 mm. of mercury is about to constitute 50 to 60 per cent of the total calcium of the serum, but an attempt to estimate the diffusible calcium in my cases, using a pressure of this amount and filtering for four hours, has given figures almost identical with those given by Drucker for ion calcium, and previous to the publication of his results I had come to the conclusion that in tetany the ultrafiltrate would contain under 2.5 mg. and usually under 2.2 mg. per cent.

Spasmophilic manifestations may, however, occur in certain circumstances with an undiminished blood calcium, indeed, some authorities have reported the presence of stenosis of infants furnishes some of the best evidence

this condition. Anyone who is familiar with this disease must have seen cases in which convulsions have occurred and recurred and eventually proved fatal, or in which—particularly shortly after the Rimmstedt operation—the child showed periods of apnoea and arrested breathing followed by a period during which deeper breathing occurred and convulsions appeared, and after several such attacks nearly always succumbed. This condition is one of all kinds of suffering from repeated vomiting and high intestinal obstruction, with the consequent loss of chlorine ions. As a result of this alkalosis, although the calcium in the serum is normal or higher than normal the ionic calcium is diminished. On the other hand in severe azotemic nephritis in which the serum calcium may be low, tetany may not occur because there is present an acidosis, which results in more of the calcium being ionized.

The therapeutic problem, therefore, becomes chiefly one of maintaining the ionic calcium at such a level (in small children over 2.2 mg per cent) that the specific effects of low calcium do not occur. Before considering how this can be accomplished I would like to refer to one or two other points in connexion with calcium concentration in nephritis and in coeliac disease. Professor Fraser has referred to the diminution of serum calcium in severe azotemic nephritis and accepted the view that this is the result of phosphate retention. Experimentally the injection of phosphates into animals and children has been found to produce this effect and also to produce tetany. Professor Fraser has suggested the possibility of administering calcium to lower the absorption of phosphate, but I doubt whether this would have any effect because of the inability of this type of kidney proper to secrete phosphate. In renal infantilism—that is infantilism associated with severe chronic interstitial nephritis—although the blood calcium is relatively low when compared with phosphorus, yet not infrequently a combination of high blood phosphorus with a normal, or even higher than normal blood calcium is found. Such a combination however is associated with severe bone changes—the so-called renal rickets. It would appear, therefore that any attempt to maintain a high blood calcium in adults suffering from severe azotemic nephritis by such methods as the administration of parathyroid hormone would produce an osteoporosis. It is true that tetany may not occur in severe azotemic nephritis, because of the presence of an acidosis favouring increased ionization of the calcium but young children are apparently more sensitive than adults to diminution in ionic calcium, and probably, therefore to prevent tetany they raise their serum calcium to a higher level than the adult by drawing on their calcium reserves. They do not always seem to do this however with the result that tetany is not an uncommon complication of this form of nephritis. As a temporary method of curing tetany in such cases parathyroid hormone might be helpful, but I have not had any personal experience of its use.

In coeliac disease the serum calcium and ionic calcium are low, as also is the serum phosphorus. If the disease be severe and of long duration rickets and tetany occur as complications, and can be cured by methods that increase the absorption of calcium and phosphorus.

Now what are the factors concerned in the absorption of calcium from the alimentary tract, and how can absorption be increased?

It has been shown that while excessive amounts of calcium in the diet tend to increase the total absorption and retention of calcium yet they impair phosphorus retention and vice versa and that the retention of one element in the intestine by an excessive amount of the other is best explained by the formation of insoluble phosphate of calcium. To obtain the maximum absorption of both elements—a necessary desideratum in infants and young children—the diet should contain amounts of calcium and phosphorus sufficient in quantity and properly balanced. The percentage of calcium in the diet should be greater than the percentage of phosphorus. In children one pint of milk daily will meet both these requirements.

Another factor in the absorption and retention of calcium is the presence of fat in the dietary and its normal absorption from the intestine. The presence of large quantities of unabsorbed fat in the intestine may lead to a negative calcium balance thus in a case of infantile biliary cirrhosis

in which, owing to the exclusion of bile from the intestine fat absorption was poor a negative calcium balance was found and in coeliac disease, a condition in which the fat absorption is very defective, a negative or low calcium retention is found. In precisely the same way a child fed on a low fat dietary may show a negative calcium balance. Thus an infant who is diet—a milk mixture containing 2 per cent of fat—contained 0.44 gram of calcium oxide in day showed a percentage absorption of 34 but when fed on a mixture containing 0.8 per cent of fat for seventeen days showed a negative calcium balance, although the daily calcium intake was more than twice as much as in the previous diet. We have found that in infants, showing a normal fat absorption, the fat intake must be from 2 to 10 grams per kilo of body weight to ensure the absorption of 0.1 gram of calcium oxide per kilo of body weight. This effect of fat on the absorption of calcium is due to the presence of the fat soluble vitamin D.

Telfer has produced evidence showing that the absorption of calcium only occurs in the upper part of the intestinal tract. The solution of the calcium salts in the food is affected by the acid of the gastric juice and absorption proceeds until the acid mixture of lime and phosphoric acid is rendered alkaline by the intestinal secretions when calcium phosphate is precipitated in insoluble form. It has therefore been suggested that an increased acidity in the upper part of the intestinal canal would increase the absorption of calcium. Such is however not entirely borne out by my observations thus in the case of biliary cirrhosis is already quoted in spite of the presence of large amounts of fatty acid in the bowel the calcium balance was a negative one and in another example of this condition the calcium absorption was very small although incidentally in both cases the absorption of phosphorus was greatly increased.

Observations have also been carried out in a number of atrophic infants fed on varying diets, some being fed on acid milk. The average calcium absorption of fourteen infants fed on lactic acid milk was considerably less than in a group of thirty-one infants fed on ordinary cow's milk mixture. This may in part be due to the fact that children fed on lactic acid milk excrete more fat than those fed on the ordinary mixtures. Four children fed on hydrochloric acid milk (that is milk prepared by adding 1 oz of decinormal hydrochloric acid to 4 oz of milk) however, showed a higher absorption of calcium and although there was a marked increase in the amount of calcium excreted in the urine the actual calcium retention was definitely higher than in children fed on cow's milk. On the other hand Wills Sanderson and Paterson found that in two children a positive calcium balance on cow's milk dietary was converted into a negative one by changing their diet to hydrochloric acid milk. Finally, a group of six infants fed on almost a food which has a buffer value similar to that of breast milk showed the highest calcium absorption of all the children examined.

Zucker and Matzner found that rats kept on a high calcium low phosphorus rickets-producing dietary developed marked renal alkalinity. It has been shown by Jephcott and Bycharach that in such animals the faecal pH can be reduced to the acid side of neutrality by means of cod-liver oil irradiated cholesterol or irradiation, and that the alkalinity can be prevented by irradiation. Indeed, they have recommended this change in pH as a test for the presence of vitamin D. It would appear then that it is not the increased acidity *per se* which is so important in the absorption of calcium as the occurrence of vitamin D, which by its presence leads to increased acidity in the intestinal tract.

The absorption of calcium from the intestinal tract is increased by giving by the mouth substances rich in vitamin D, such as cod liver oil irradiated cholesterol irradiated ergosterol or by exposure to sunlight and ultra-violet irradiation.

The problem of how to increase calcium absorption in coeliac disease is complicated by the difficulty in absorption of fats in this disorder and because for its efficient treatment it is necessary to give a very low fat dietary for a long period or time. Actually when the fat in the diet is kept very low indeed the percentage absorption is

increased, but to prevent or to cure rickets and tetany either ultra-violet irradiation or the giving of irradiated cholesterol or ergosterol is essential. The administration of irradiated cholesterol or ergosterol appears to produce better results than exposure to ultra-violet light, but it is advisable to combine both forms of treatment. Irradiated cholesterol or ergosterol must not be given dissolved in oil, as recommended in ordinary rickets and tetany. I administer irradiated cholesterol in powder form and ergosterol in tablets prepared by the British Drug Houses, Ltd. Incidentally these tablets also contain 2 grains of calcium glycerophosphate, but I am sure that the additional calcium is unnecessary.

As I stated in my opening remarks, the number of cases in which I administer calcium salts is such is small, being almost entirely limited to the acute stages of tetany, in which I give calcium chloride in 5 to 15 grain doses three times daily. In all other cases I find the calcium in the diet (chiefly milk) amply sufficient to produce the calcium effect if absorption be improved by the methods suggested. It is stated by some authorities that cow's milk should never be given in tetany, because of the tendency of some infants to constipation with the passage of large soap stools, which contain considerable quantities of calcium soaps and therefore deplete the body of calcium. This type of nutritional disturbance, which in its severest form has been particularly stressed by German workers (Czeiny, etc.) under the title of *Milchnahshaden*, is in my experience a very rare occurrence. I am not convinced that even in these rare cases the loss of calcium in the soap stool is sufficient to overcome the advantages of the good calcium supply obtained by giving a milk diet, but that there is a certain loss of calcium in children passing soap stools cannot be denied, and therefore there may be some advantage, in those cases of tetany which are complicated by constipation, in substituting almond for milk for a time, and further justification for giving calcium salts in the acute attack.

In the cases of spasmodophilia due to alkalosis, to which reference has been made, the methods used to alter the blood reaction and thereby increase the ionic calcium are to give saline intravenously, to operate at once in cases of pyloric stenosis, and to fill the abdomen with normal saline, after operation to feed the infant on lactic acid milk if breast milk be unobtainable, in order to prevent the drain on the body chlorine ions caused by the high buffer value of cow's milk and the necessarily greater amount of hydrochloric acid required for peptic digestion. I must also confess that in a recent case of alkalosis tetany (a boy aged 14) I gave 15 grains of calcium chloride intramuscularly in addition to intravenous salines, with most encouraging results.

### III—THE BIOCHEMICAL ASPECT OF CALCIUM THERAPY

BY

C. P. STEWART, M.Sc., Ph.D.,

Lecturer in the Department of Medical Chemistry, University of Edinburgh

THE inconstant results obtained in feeding various calcium salts and various calcium-containing foodstuffs are possibly to be explained as the result of the observation that in health the intestinal contents remain slightly acid, while in rachitic animals they are alkaline. In the presence of a copious secretion of hydrochloric acid in the stomach such salts as the lactate, carbonate, and proteinate of calcium would all give rise to calcium ions, which, the reaction remaining acid, would be available for absorption from the intestine. In the absence or reduction of such a secretion these salts would not be ionized to the same extent, and therefore would be less readily absorbed. Other inorganic substances must be taken into account. Thus it is readily seen that a large excess of phosphate would hinder calcium absorption, since, in consequence of the slightly acid reaction of the intestine, some of the calcium would form the insoluble phosphate.

A careful distinction must be made between calcium absorption and calcium retention: the latter is measured

simply enough by taking the difference between intake and output, estimation of the former is not so easy. Alterations in the urinary excretion are of little value, as the greater part of calcium excretion occurs through the epithelium of the large intestine. Determinations of the blood calcium content are perhaps better, but still unsatisfactory. As an example of the confusion some recent experiments by Berggren, who has devised a method for measuring the actual absorption, may be mentioned. He finds that in rachitic animals calcium is absorbed from the small intestine only to be excreted again into the large intestine. Vitamin D improves the retention (though it seems to be that this is not necessarily the sole effect of the vitamin). By removing the whole of the alimentary canal from experimental animals Dr. Perival and I have been able to show that the parathyroid hormone does not raise the blood calcium by increasing absorption from the intestine, for in the eviscerated animals the effect of the hormone is as great as in intact animals. By isolating the large intestine and washing out its contents we estimated the calcium excretion by that route. The urinary excretion was used to determine the parathyroid hormone, we found, did not diminish calcium excretion—that is, it did not increase retention. It must act, therefore, by withdrawing calcium from the tissues, and ultimately, at any rate in long-continued hypercalcaemia, from the bones. Greenhalgh has shown that in a hypercalcaemia induced by parathyroid hormone the excretion is increased, and that there is a calcium loss from the body. It follows that parathyroid hormone is of no use where it is desired to increase calcium absorption. Further—especially where the absorption mechanism is impaired—its long continued use to raise the blood calcium level may lead to the undesirable effect of depletion of the body stores.

Calcium circulates in the blood stream, and it may reasonably be assumed that in this, as in other cases, changes in the tissue content will be, to some extent at least, reflected in the concentration in the blood. Moreover, though on this point there remains a slight element of doubt, it seems that the calcium of the blood is confined to the plasma and that the corpuscles contain at the most only traces. Hence the plasma calcium content forms a valuable guide as to the state of the animal with regard to calcium metabolism. True plasma is difficult to obtain, and experiments with citrated plasma, based on the assumption that sodium citrate does not precipitate any calcium, have led to the statement that the plasma and serum contain equal amounts of calcium and, consequently, to the universal use of serum for calcium estimations. Actually, true plasma contains 10 to 20 per cent more calcium than does the serum, but for most purposes this does not destroy the usefulness of the serum estimations as an index of normal functioning. Figures obtained by analysis of serum are certainly of more value than those obtained from whole blood, owing, inter alia, to the variability of corpuscle volume.

Of the 10 mg. of calcium normally present in 100 c.c. of human serum only some 2 mg. exist as calcium ions, and only about 6 mg. are able to pass through a colloidal membrane. The remaining 4 mg. are in some form of combination—part as an ionized salt or complexes of protein, and part, possibly, in an ionized combination with lipid material. Whether the plasma calcium is distributed in a similar manner we cannot say with certainty. Vines's work would appear to indicate that it is not. On the other hand, evidence derived from the analysis of the cerebro-spinal fluid and of cerebrospinal fluid which have been enclosed for some time in the peritoneal cavity, indicate a similar distribution of calcium in serum and plasma.

Holt, La Mer, and Chown believe that the blood is supersaturated with calcium phosphate,  $\text{Ca}_3(\text{PO}_4)_2$ , to an extent of more than 200 per cent, since on dilution with solid calcium phosphate there is a reduction in the calcium and the phosphate concentrations, although no such reduction takes place in the absence of the solid phase. They explain the supersaturation as due to a sudden change during absorption from the acid reaction of the intestine to the alkaline reaction of the blood.

change which causes the production of trivalent  $\text{PO}_4$  (from monovalent  $\text{H PO}_4$  and divalent  $\text{HPO}_4$ ) at a rate greater than the calcium phosphate can be precipitated. Though this is an extremely interesting suggestion—it implies, for example, that the fluids bathing osteoid tissue are supersaturated with calcium phosphate in presence of the solid phase a condition which would lead to deposition of more solid calcium phosphate—Holt, La Mer, and Chown do not seem to have taken into account sufficiently the presence of bicarbonate and of a large part of the serum calcium in the form of non diffusible protein or lipid complexes. Indeed, it has also been claimed that blood is supersaturated with respect to calcium bicarbonate.

The diffusible and especially the ionic, calcium of the plasma is doubtless most readily available for transference to other tissues, and is often referred to as the "active" or "available" calcium. In using these somewhat dangerous terms, however, two things must be borne in mind. In the first place we really know nothing about the functions of the different calcium derivatives present in the blood and it is perfectly conceivable that the non-diffusible fraction may have its own special uses. Secondly, neither the absolute nor relative concentrations of the different calcium compounds can be regarded as fixed and immutable; they form a series of mutually dependent equilibria so that alteration in the concentration of one constituent may be followed by a readjustment throughout the whole complex system.

#### IV—PHARMACOLOGICAL AND THERAPEUTIC ASPECT

BY

G. H. PERCIVAL, PH.D., M.R.C.P.

(From the Pharmacological Laboratory, University of Edinburgh.)

It has already been emphasized, in the opening paper, that the presence of calcium is necessary for the life and activity of the various cells and systems of the body. It is not possible, however, in view of the existing state of our knowledge to present a coherent account of its exact mode of action or to offer an explanation of its indispensability. Such explanation must await the solution of a multitude of physical and chemical problems of the most complex and fundamental nature. Certain facts, however, have long been known.

In the first place, Sidney Ringer determined the concentration of calcium required to maintain the normal activity of the frog's heart and noted the effect on it of variations in this amount. Later workers have studied the effect of calcium-containing solution on other tissues and also on the less highly organized forms of life. Many of the experimental results obtained have been questioned, and the interpretation of those which are now generally accepted is by no means clear. There is nevertheless an increasing amount of evidence in favour of the theory that calcium is intimately associated with the lipid complexes of the cell membranes and that variations in the calcium content of the fluid bathing the cells tend to produce alterations in the physical structure of these complexes. The property of semi-permeability possessed by the cell membrane is thus interfered with and the activity of the cell modified accordingly. The general action of calcium appears, therefore, to be exerted at the surface of the cell.

Experiments on the lower animals have shown that certain tissues, notably the cardiac and skeletal muscles and the nerve, are extremely sensitive to slight variations in the calcium content of the fluid in which they are bathed. Presumably this is so in the human subject, and, as has already been stated by Professor Fraser, the calcium concentration in human serum is found to be remarkably constant. In certain diseases, however, considerable variations do occur and it is worth noting that it is only when the serum calcium has been reduced to from 60 to 70 per cent of its normal value that symptoms which can be attributed to such a diminution make their appearance. The most constant change accompanying such a reduction is increased excitability of the peripheral nerves to electrical, and to a less extent to mechanical stimulation and it

would seem, therefore, that these structures are more sensitive to lack of calcium than are the more delicate organs such as the heart and the central nervous system. On the other hand, an increase of 20 to 50 per cent in the serum calcium, such as has been found in osteitis fibrosa, is unaccompanied by any symptoms apart from those associated with the local bone condition. Nevertheless, despite the fact that wide variations in the serum calcium are compatible with the apparently normal functioning of the body cells, there exists a very efficient mechanism for controlling the concentration of this substance in the serum.

Various factors are concerned in this control—the availability of the ingested calcium, the body stores, the reaction of the tissues, the presence or absence of vitamin D, and the parathyroid hormone. Before continuing it may be well to emphasize the delicate correlation of all these factors. In the first place, the remarkable constancy of the serum calcium, not only among different individuals, but also in the same individual. Further the alteration of one of these factors produces a very rapid response—for example, the intravenous injection of sodium bicarbonate or parathormone produces its maximum effect within an hour, and the return to normal is equally rapid. Moreover, by simultaneous injection of appropriate doses of these substances it is possible to maintain the serum calcium unchanged. It may also be mentioned that in rickets vitamin D may be quantitatively deficient without more than a slight fall in the serum calcium. Again, severe haemorrhage producing a 50 per cent reduction in the haemoglobin is unaccompanied by any fall in the serum calcium of dogs and cats, animals which are sensitive to the parathyroid hormone, whereas in the relatively insensitive rabbit such haemorrhage causes a definite lowering of the serum calcium. This evidence besides illustrating the delicacy of the controlling mechanism in toto, also points to the parathyroid hormone as being the chief controlling factor.

Turning now to survey the results of calcium administration in disease it is not surprising to find, in view of the foregoing facts, that calcium as a therapeutic agent has proved most disappointing. The large available store of calcium in the bones and the constant supply in the daily food intake make it extremely unlikely, except in very rare instances, that the regulating mechanism ever lacks calcium for distribution throughout the body fluids, so that it is only in the event of failure of function of some part of this mechanism that the tissues suffer from calcium deficiency. Shortage of vitamin D may either cause deficient calcium absorption from the bowel or interference with the process of ossification and in these circumstances no amount of calcium given by the mouth or intravenously is likely to alter the degree of its utilization by the tissues.

In the case of parathyroid deficiency a different set of factors is operative, and there is primarily no interference with absorption. A temporary rise in the serum calcium, with a coincident alteration of symptoms, may be produced by the oral administration of calcium, as well as by its intravenous injection. The effect is only temporary, however, for the function of regulating the distribution of calcium between the blood and the body fluids has been lost. Calcium therapy, therefore, is merely palliative.

Spasmodophilia is also temporarily relieved by the administration of calcium salts although the accompanying rachitis is not benefited. In this instance there is no doubt that calcium can be absorbed from the intestine in sufficient amounts to raise the serum calcium above the tetany level, even at a time when the tissues are suffering from a deficiency of vitamin D.

A consideration of pregnancy reveals a sequence of events which may lead to another variety of deranged calcium metabolism. The constant demand on the part of the growing foetus for calcium obviously subjects the maternal tissues to a severe strain, and in some cases these may be taxed beyond physiological limits. Animal experiments have demonstrated the fairly frequent occurrence of a negative calcium balance during pregnancy and lactation. One obvious cause of this derangement is that the maternal diet contains an insufficient amount of calcium to meet the requirements both of the maternal organism and of

the foetus, although sufficient for the former alone. Again, in the human subject the serum calcium is frequently somewhat diminished during the later weeks of pregnancy, and a low serum calcium has been found in cases of eclampsia. These facts would warrant attention being paid to the supply of a liberal daily ration of calcium in the maternal diet throughout the periods of pregnancy and lactation.

The condition of osteomalacia occurring in pregnancy cannot be definitely attributed, however, to a mere deficiency in the supply of calcium, since its course is not arrested by the administration of calcium. The biochemical methods now available do not yet appear to have been applied to an investigation of the etiology of this condition, about which very little is definitely known. In the allied condition of osteitis fibrosa, where decalcification of bone is also the most striking feature the serum calcium has been found to be very much higher than normal, and adenomatous tumours of the parathyroid glands have been present in a number of cases. These findings suggest that the condition is due to the occurrence of hypersecretion of the parathyroid glands, and this would account for the failure of calcium therapy.

The conditions which have been so far dealt with have all presented definite abnormalities in calcium metabolism, the mechanism responsible for this derangement has been to some extent accounted for, and the value of calcium therapy discussed.

Calcium therapy has been advocated in numerous other diseased conditions on purely empirical grounds. In many of them this method of treatment has been credited with quite remarkable curative effects, but in the majority of cases these have been discredited after a more prolonged and extensive trial. There remain however certain conditions in which calcium is still recommended but in which there appears to be no indication for its administration, either in view of the pathology of the disease or of the clinical results obtained by such medication. It has recently been revived in the treatment of chronic infective conditions, on the assumption that the serum calcium is either diminished in amount or that there is some alteration in its physical condition. Impairment of the defence mechanism of the body against organismal infection is said to be brought about by such a change, with the result that chronicity is favoured. The condition quoted as an outstanding example of this type of derangement, and as benefiting from calcium therapy, is that of chronic leg ulcer. It may be definitely stated, however, that in this disease the serum calcium is normal both as regards its concentration and its physical state, and that the raising of the serum calcium and the alteration of its physical state by administering calcium salts and parathyroid extract does not hasten recovery. The same may be said of the various forms of inflammatory and infected skin lesions and of chronic rheumatism.

Another group of diseases in which an attempt has been made to obtain relief by the administration of calcium is that resulting from a lack of tone in the superficial vessels of the extremities with consequent circulatory stasis in the capillaries and venules. This gives rise to a group of closely allied symptom complexes, including erythema pernio, "raw beef" hands, and chronic erythema of the legs, and is an almost invariable precursor of erythema induratum. Calcium has long been advocated in erythema pernio, and the apparent success of this treatment has led to its trial in the closely allied disorders mentioned. In none of these conditions, however, are there any grounds for concluding that calcium therapy might be efficacious. In all of them the serum calcium is normal, both as to amount and physical state, and clinical benefit does not follow the administration of calcium alone or combined with parathyroid extract, even when a very definite alteration in the serum calcium is obtained by such means. In erythema pernio sudden and extreme variation in severity is a clinical characteristic of the condition and is responsible for the reputation gained by calcium as a curative agent, for in those somewhat rare examples which are persistent calcium therapy proves a failure.

It would appear that derangements of calcium metabolism

are confined to a very small number of pathological conditions, and that, with a possible exception in the case of pregnancy, such derangements are almost always due to a deficiency in some part of the controlling mechanism. For this reason calcium therapy appears to have a very limited field moreover, in those instances in which it has proved useful the effects are merely palliative, and may be better achieved by other means.

#### DISCUSSION

Professor L. BLUM (Strasbourg) discussed the administration of calcium salts as a therapeutic measure in cases of nephritis, with ascites and oedema. He illustrated with diagrams and tables the results which he had obtained. In certain cases, where no diminution of ascites or oedema had followed resort to a salt-free diet or the administration of diuretics, large doses (10 to 20 grams a day) of dry calcium chloride had given rise to copious diuresis with consequent relief of ascites. He had found that, to obtain the effect, the calcium chloride must be added to an otherwise completely salt-free diet. The effect was much less marked if other salts were given with the calcium. The lactate was much less effective than the chloride. If the calcium chloride was replaced by sodium chloride there was an immediate and marked increase in the dropsy. Oedema due to other causes was more refractory to calcium treatment. When the condition was caused by cirrhosis of the liver such drugs as iocasinol were definitely indicated. In such cases calcium salts might merely be given and were on the whole useful. In cases of pleurisy, Professor Blum had observed that the administration of large doses of calcium chloride was followed by clinical improvement, and a fall in temperature and pulse rate. The diuresis in such cases was small, because the actual fluid retention was usually not very great. It was not advisable to continue the administration of calcium for too long a period. Professor Blum then discussed the condition which he had named "dry chloride retention," in which the chief factor was a disturbance of the ratio of sodium and chloride ions in the tissues, particularly in the brain, the proportion of chlorine being raised and that of sodium diminished. In both body fluids and tissues the balance between sodium and chlorine ions,  $\text{CO}_2$ , and "protein acid" was disturbed giving rise to an alteration of hydrogen ion concentration. The administration of large quantities of calcium chloride might give rise to this condition of "dry chloride retention." In the pure "hydratic" type of nephritis the chloride retention affected only the fluids, the ionic relation in the tissues was normal. Professor Blum admitted that in these cases the increase of chlorine ions appeared to be the potent factor, but some definite and specific effect was also assignable to calcium ions.

Dr. G. C. LINDER (London) said that tetany was a response of the body to several different chemical states which fell, however, into two groups. In the first of these were infantile parathyroid, intestinal, and phosphatic tetany in all of which the serum calcium was much decreased, in the second were gastric bicarbonate, and over-breathing tetany, in which the serum calcium was normal, but its effectiveness was reduced by such abnormalities as increases in pH, bicarbonate, or phosphate. Calcium salts were effective in the first group. Intravenous calcium chloride immediately and completely relieved the symptoms. 2 grams were required in the case of an adult with parathyroid tetany and the effect passed off with the excretion of the calcium in a few hours. The salt would not be sloughing if it passed outside the vein, this treatment is therefore, an emergency one. By the mouth calcium chloride was less certain. In doses of 10 grams a day it gave dramatic relief to the symptoms of a patient with intestinal tetany, but this was probably due not so much to the small rise in serum calcium as to the accompanying changes in pH and bicarbonate, since calcium chloride in the mouth was a powerful agent in the production of acidosis. Determinations of calcium excretion showed that a large amount of calcium was retained in the body although the serum calcium rose but little. When 20 grams of calcium lactate were given instead of the chloride

to a patient suffering from tetany, active tetany at once appeared but disappeared again after two days it was probably due to the readjustment of the acid base balance. A slow increase in serum calcium followed, and the patient remained free from active tetany. A return to calcium chloride was followed by a prompt rise of the serum calcium to normal figures, and the signs of latent tetany disappeared. The body now, after fifty days of massive calcium therapy behaved as though it were rich in calcium and responded to parathormone (Collip) in a way in which it had failed to do before. More difficult to interpret were the results obtained in the treatment of a case of parathyroid tetany, 150 units of parathormone with 6 grams of calcium lactate were comparatively ineffective, but when foci of sepsis were removed and calcium chloride substituted for calcium lactate there was immediate clinical and chemical improvement on a much lower dose of parathormone. It was suggested that sepsis vitiated the action of parathyroid extract as it did that of insulin. The calcium chloride was probably effective more by its acid effect and by promoting a fall in serum phosphate than by virtue of its calcium ion. Ammonium chloride would probably have acted equally well. In this case, also, prolonged calcium therapy enabled parathormone to develop its full action. No experiences with cases of tetany of the second group were available, but it seemed probable that in all of them calcium chloride by the mouth would be of benefit by its effect in proving an acidosis. By way of absorption of calcium it would be of no value, calcium lactate should therefore not be given.

Dr NORMAN BURGESS (London) stated that for the estimation of the serum calcium he had employed the method described by Lindlaw and Payne in 1922. Pathological cases showing a diminished serum calcium fell into two groups, in the first the total calcium was normal while the precipitable calcium was low, in the second both total and precipitable calcium were markedly diminished. Dr Burgess then discussed the biological method employed by Vines, which depended on the recalcification of oxalated blood by the addition of the material to be tested and the comparison of the action of the latter with that of calcium chloride solutions of known strength. Vines and Grove found that injection of calcium chloride or administration of parathyroid increased the readily precipitated calcium in the serum, and that clinical improvement accompanied this increase. With reference to calcium metabolism in skin diseases Dr Burgess's work included the investigation of sixty-seven patients of which the majority were cases of urticaria, prurigo, or acrosphegia. Of the urticarial cases a clinical distinction could be made between those in which dermatographism was a marked or predominant symptom and those in which it was absent or slight. Of the former four cases were examined, and with out exception gave a very low figure for the precipitable calcium, while in three cases the total calcium was normal. In one case the dermatographism was so marked that rubbing the face and hands with a towel caused them to become swollen. Following treatment with calcium chloride and parathyroid extract after meals, the patient's condition became practically normal. In another case, after twelve days' treatment the precipitable calcium had risen from 3.9 mg to 8.5 mg per cent, and there was considerable clinical improvement. All the patients without dermatographism showed a diminished precipitable calcium, but the figures were not so low as in the former cases. The prurigo was mostly of the Besnier type, associated with ichthyosis, a thymic, hay fever, and eczema, only one of the sixteen patients gave a normal figure for the precipitable calcium. In the majority of the cases the total calcium was normal. In one case associated with vitiligo, the precipitable calcium rose from 5.3 mg to 9.75 mg per cent after one month's treatment with calcium chloride and parathyroid extract, and the symptoms disappeared. On the whole a considerable improvement had been noticed in the majority of these cases of prurigo under treatment with calcium and parathyroid. Of fourteen cases of acrosphegia eight gave normal figures for the total and precipitable calcium while in the remainder the precipitable calcium was much diminished. Two cases of generalized alopecia areata gave

very low figures for the precipitable calcium, the total calcium being slightly below normal. Of four cases of psoriasis only one gave a low figure, the rest being practically normal. In seven cases of eczema the precipitable calcium was lower than normal. One case examined after treatment showed considerable improvement, and the precipitable calcium had risen from 4.5 mg to 7.5 mg per cent. The total calcium was normal in five cases and slightly diminished in two. In all the cases of light sensitization (adult type) examined the precipitable calcium was lower than normal, the total calcium being approximately normal. Five cases of subcorneal dermatitis were investigated, of which two were normal, one showed slight diminution of both total and precipitable calcium, while the other two showed marked diminution of the precipitable calcium. In two cases of total alopecia areata there was a diminution both in total and in precipitable calcium, but particularly in the latter. One case of erythema multiforme showed a slight diminution, while a case of Darier's disease and another of xeroderma pigmentosum both gave normal values. Dr Burgess added that it was clear from the results obtained in this series of cases that the precipitable calcium of the serum tended to be diminished in those diseases which were associated with involvement of the sympathetic or endocrine-sympathetic systems, such as urticaria, particularly when associated with dermatographism, prurigo, especially in the ichthyosiform, hay fever, prurigo syndrome, acrosphegia, and alopecia areata. Good results might be expected to follow treatment with parathyroid extract and calcium when the precipitable calcium was low in cases of urticaria with dermatographism, encouraging results had been obtained in some cases of prurigo.

Dr C. G. LAMAR (Edinburgh) said that osteitis fibrosa was a chronic disease characterized by rarefaction of the bones, the presence of bone tumours containing giant cells, and by hyperplasia of the parathyroid glands, the latter being sometimes as large as a pigeon's egg and easily palpable in the neck. This coexistence of osteoporosis and enlargement of the parathyroids suggested some connexion between the two, and led him to examine the calcium metabolism in such cases. A marked hypercalcaemia was found, the amount of calcium present being 17 mg per cent, a figure comparable with that found by Collip in dogs injected with large doses of parathyroid extract. The blood inorganic phosphate was slightly lowered, but the acid soluble phosphate was normal. The magnesium chloride, urea and non protein nitrogen were normal. The clotting time of the blood was unchanged. The CO combining power of the blood was increased by 5 per cent, perhaps owing to the increased amount of base in the blood brought about by the hypercalcaemia. The patient was kept on a diet of milk alone and his calcium balance was tested over a period of a week. The output of calcium in the urine was about normal, but there was a considerable increase in the output of calcium and phosphate in the faeces, the result being negative calcium balance for the period of observation. These findings were similar to those found by Greenwald and Collip in dogs treated with parathyroid extract, and suggested that the decalcification of bones was due to excessive secretion of parathyroid hormone by the hyperplastic parathyroid, the effect of the hormone being to cause the mobilization of calcium in bone. If this interpretation was correct, osteitis fibrosa would be a metabolic disorder, analogous to acromegaly or exophthalmic goitre and not merely a disease of bone. While the parathyroid hormone brought about the mobilization of calcium in bone, the effect of vitamin D appeared to be to promote the synthesis and deposition of calcium phosphate. The value of vitamin D as a therapeutic agent was not confined to rickets. He had found it raise the blood calcium to normal in a case of fragilitas ossium. It also seemed possible that some of the benefit of cod liver oil, ultraviolet irradiation and sunlight treatment in tuberculosis was associated with the increased deposition of calcium phosphate around tuberculous foci, thus aiding in the natural process of cure. It appeared significant in this connexion that this treatment was most efficacious in tuberculosis of bone and glands.

CONVULSIONS CAUSED BY PITUITARY EXTRACT  
AFTER LABOUR

The following extraordinary reaction to a therapeutic dose of pituitary extract merits a short description, as such an event does not seem to have been recorded before.

The patient was a fat multipara, aged 40, who had suffered from typical diabetes for some seven years, and had been treated with insulin during her last pregnancy. On September 16th, 1927, a stillborn foetus weighing 12½ lb was delivered after a difficult forceps operation, the cause of death being haemorrhage from a tear in the tentorium cerebelli.

Insulin was stopped after labour, without sugar or acetone appearing in the urine.

Ten days after delivery the uterus was lax, and 10 units of pituitary extract (1 ccm pituitrin) were given intramuscularly at 11.20 a.m., and produced a very alarming condition which had at one time the appearance of being fatal. At 11.30 the patient complained of faintness. At 11.40 she felt sick and retched but did not vomit anything. Beads of sweat covered her face, which was ashy white. She asked urgently for the bedpan and began to pass a liquid motion, when she collapsed forward as she was being held on the pan. Her head drooped, the eyes were closed, she breathed heavily and seemed quite unconscious. She was laid flat in bed and then became stiff all over like the tonic stage of epilepsy, and the firmly clenched jaws had to be propped open to prevent her biting her tongue severely. The breathing was heavy stertorous, and obstructed, and her colour, which had been white, became blue and cyanosed. At 11.50 the pulse rate was 140 and the systolic blood pressure 70 mm., as far as could be made out. She began to recover consciousness and at noon scratched her head and stomach fiercely and asked what was the matter with her. For a few moments muscular twitches occurred and were especially violent in the jaws and hands. She was very confused mentally and asked for her husband whom she appeared to think was just outside, and for the baby which had been stillborn four days previously. At 12.5 p.m. the pulse rate was 120 and she complained of headache and itching and trembling all over. She was very restless, afraid she was going to die and wanted to sleep but could not. At 12.30 the bowels were opened and she complained that she could not see. She slept for short snatches and at 1.15 said that she could see better but felt very cold. The pulse was 120. At 2 she vomited three times, but her mind was becoming clearer. By 4 o'clock her mentality was quite normal and the pulse rate 116. At 6 p.m. the blood pressure had risen to 96/52 which is her usual pressure. Two hours and a half after the dose of pituitrin the blood sugar was raised to 0.188 per cent, although no food was given, she passed a considerable amount of sugar that evening and traces for the next few days, whereas she had been sugar free before this attack. She felt quite well on the day after the attack.

So far as we are aware there is no record of such a severe attack after pituitrin, although pallor, dizziness, and cold are common enough. The course of this patient's diabetes (which will be published later) suggests a hyperactive pituitary, and the bitemporal constriction of the fields of vision suggests the same thing, although no definite homonymous symptoms are present. The severity of the symptoms experienced after the pituitin may therefore be due to an overactive pituitary gland.

## INVERSION OF THE UTERUS

In view of the case of uterine inversion reported by Dr J. C. Fotheringham in the JOURNAL of August 27th (p. 350) it may be of interest to record details of a patient I attended for the same condition.

A woman, aged 22, sent for me to attend her at her first confinement on July 20th, 1927. With the aid of forceps I delivered her of a normal healthy female child.

The placenta appeared somewhat adherent so I allowed forty minutes to elapse before making final efforts to express it, it came away without undue pressure, but when I attempted to separate it by torsion I found the inverted body of the uterus in my hands. I peeled the placenta from the endometrium and examined the latter, the surface appeared plum coloured and of a velvety consistency with a few oozing points of blood here and there, but no excessive bleeding. After the nurse had migrated the exposed surface with saline solution I endeavoured to reduce the inversion but failed. Since the patient showed signs of collapse I made no further efforts except ordering hot saline douches night and morning and general stimulating diet. Ten days later under a general anaesthetic I reduced the inversion by taxis which took about fifteen minutes. The patient made an uneventful recovery, and is now perfectly well.

There was very little haemorrhage in this case, but the evidence of shock and collapse at the time decided me to hold my hand till a later date, this was justified by the result.

Hove, Sussex.

COMPOUND FRACTURE OF THE HUMERUS  
SPONTANEOUS REPAIR

The following case is of interest on account of the unusually good result which followed such primitive treatment of the fractured arm.

An East African (Swahili) boy, aged about 14, applied for treatment at the native hospital Dar-es-Salaam, Tanganyika Territory, in 1926 complaining of 'the bone of the arm' (right).

The history given was of a fall from a tree 'several months before', owing to the usual native inability to reckon time of time this was the nearest estimate of the period which could be obtained. As a result of the fall the right upper arm was broken at about its middle and bone protruded from a wound. The patient stated that he himself tied a stick to the injured arm, and that he kept the stick on for about two months. He then removed the stick, and found that he had some movement of the arm but the bone still protruded. His power of movement of the arm continued to improve, but the bone did not go away, so he came to a white doctor for treatment.

Briefly, on examination there was seen some slight wasting of most of the muscles of the right arm compared with the left, and some outward bowing of the upper arm. At a point about the junction of the middle and lower third of the upper arm, and just external to the lower part of the biceps muscle was protruding a jagged piece of bone about three quarters of an inch long, surrounded at its base by scar tissue, which appeared healed and clean. On seizing the projecting bone only slight movement of it could be effected. The right humerus seemed intact and the movements of the right arm were only slightly limited compared with those of the left. There was no pain or tenderness and no shortening could be made out on measurement. There was no evidence of nerve involvement.

A radiogram showed that the humerus was intact with outward bowing and some thickening at what was presumably the old site of fracture. There was a detached fragment leading from this point downwards and outwards and ending outside the flesh shadow, with some periostitis at its base. With simple expectant treatment the fragment was eventually withdrawn with forceps, and the resulting sinus healed quickly.

The photograph is of the case shortly after it was first seen. Such a good functional result after such crude treatment must be very exceptional, and it is an interesting conjecture as to what could have been the original bone injury.

## THE "RISING TEST" FOR ACUTE ABDOMINAL

For the last two years I have been using a test, both in private and hospital practice, which has proved exceedingly useful—more especially in those borderline cases (chiefly cases of appendicitis, where one might reasonably be persuaded to put off operation, perhaps until the next day or so).

The "rising test" consists in the patient putting both hands down by the side of the thighs and then rising himself in bed by means of the abdominal muscles. This produces pain immediately, and the patient fails to rise himself or complains of pain in doing so. This test will prove positive when there is little or no tenderness in the abdomen. In my hands it has frequently proved the presence of acute abdomen, and is often the decisive factor in doing an immediate operation. The test is a sign of an acute abdominal condition, not necessarily appendicitis, and applies equally well in any acute abdomen.

The rising test has been tried by a physician in a large teaching hospital, who writes to me that it is working well.

C. L. GRANVILLE CHAPMAN, F.R.C.S.,  
Surgeon, Grimsby and District Hospital.

## CONGENITAL OCCLUSION OF THE SMALL INTESTINE

THE following case resembles in some respects that described by Dr B. Sher in the BRITISH MEDICAL JOURNAL of September 24th (p. 549)

A male child the seventh in the family was born in December 1926. He was well nourished and weighed 8 lb. He passed no meconium but some green mucus and the anus admitted the little finger. At first he took the breast well but on the third day he began to vomit about half an hour after feed first bile-stained fluid and later faecal material. This continued with increasing distension of the abdomen till he died on the sixth day.

At the necropsy it was found that the distended upper coil of the small intestine ended in a bulbous part. There was about an inch of intestine with a tiny cord attached to its free border then another much smaller bulb continuous with the lower intestine of about 12 inches. The caecum and other parts of the large intestine were present and rotated perfectly. But they were very small in size. There was an intussusception of the ileum, probably agonal as it was not inflamed about an inch below the occlusion, and an inch and a half in length.

The mother had been treated for syphilis during previous pregnancies but her Wassermann reaction was negative. Several small lymph glands in the intestine near the occlusion were examined for spirochaetes by Dobell's method but none were found.

Sunbridge Well.

SIDNEY E. CROSEY, M.B., Ch.B.

## Reports of Societies.

### THE FUTURE OF RADIOLOGY

At the first seasonal meeting of the Section of Electrotherapeutics of the Royal Society of Medicine on October 21st Sir HENRY CANNAN delivered his presidential address, and three short communications were made by distinguished visitors from the United States, Denmark, and Switzerland respectively who had been elected corresponding members of the Section.

Sir Henry Cannan said that he took his election to be an indication that the Section regarded the science of electrotherapeutics as embracing the whole range of electromagnetic vibrations in their application to the relief of human suffering. It was no exaggeration to claim that no branch of medicine could record such rapid advances of recent years. A century ago few could have conceived that by submitting the subject to forces impalpable, invisible, and intangible the inner secrets of the human structure could be clearly revealed, malignant growths dispersed and rickety bones restored to normal. Though it was not yet to be explained how these and other effects were produced, they were so readily and certainly achieved that they had ceased to be surprising. Whither would these forces lead? It was right to give rein to the imagination if, as in this event, the imagination sprang from a foundation of facts already familiar. It would be alluring to discuss the possible future developments of electrotherapeutics but there were present in the Section three distinguished visitors from other countries who would indicate some recent advances for which they were responsible. He would make only one personal observation. It appeared to him that the advance which electrotherapeutics was making in all its applications was so rapid and important, so pregnant with possibilities, that not only was the employment of highly expert practitioners called for in this branch of scientific medicine but it was imperative that all medical practitioners should have a certain clear knowledge of the principles and practice of electrotherapeutics. The time had come when all medical students should have systematic instruction in these methods. The status of the radiologist on the staffs of teaching hospitals should be improved. The advent of a diploma in radiology was to be welcomed but it was not enough. It might encourage more specialization in this branch of medicine and that was a good thing but what was more needed was a larger general knowledge amongst medical men of the significance and importance of the subject. The electrotherapist should have equal rank with the physician and surgeon. Not only should he have his department which should not be considered a subordinate depart-

ment to any other, but he should have his own wards, beds and teaching facilities. The interests of patients demanded that the proper recognition of this branch of medicine should not be farther delayed.

### Radiological Methods in Diagnosis of Pulmonary Tuberculosis

Dr H. K. DUNHAM (professor of electrotherapeutics, University of Cincinnati), who addressed himself to the subject of radiological methods in the diagnosis of pulmonary tuberculosis, said that the radiologist, if he hoped to help the clinician in medicine, must translate for him x-ray densities into pathology. To do this it was necessary to use the stereoscopic method, by which alone it is possible to make useful study of the shadows with their pathological significance. In the single plate one of the subtler variations of density as between different areas were apt to be lost. Dr Dunham exhibited a large number of radiograms of chest conditions, and pointed out the markings which showed the stage and condition of the tuberculosis. A number of the examples were included to illustrate what he called the fan indicating tubercle is producing exudate. It was, he thought, too common in the United States for radiologists, while anxious to ensure that their radiological methods were sufficiently perfected to detect the earliest signs of tuberculosis, to fail to realize, what he thought was the greatest value of x-rays in this connexion, that the x-ray method enabled the physician to exercise care and control over the whole progress of the case. He also begged radiologists not to try to do too much, they should concentrate on giving the clinician some definite information relating perhaps only to a small fact rather than make a guess at something on which their methods did not enable them definitely to pronounce. Locked up in the x-ray plate was pathology. The x-ray pictures must be translated back into pathology, and the clinician must translate back into pathology his physical signs. Without this, the work on the chest would be lost to a large extent.

### Treatment of Pulmonary Tuberculosis by Modern Methods

Dr J. CHRISTENSEN (medical superintendent Vejlebjerg Sanatorium, Denmark) also showed a number of lantern slides illustrating some recent results in the treatment of tuberculosis. He dealt with the effect of artificial pneumothorax and sanocrysin, both had reduced the number of failures in tuberculosis treatment, and had greatly shortened the period. The reason why such different opinions were expressed with regard to the chemotherapy of tuberculosis was that the good effect of the agent was not to be expected in all tuberculosis cases, but only in those where there was evacuation or fresh spread. The sanocrysin specific treatment covered those cases in which the affection was of an exudative character. Artificial pneumothorax covered just those cases in which sanocrysin failed, it was useful where there was fibrosis of the lungs of a chronic type which did not react well to the ordinary sanocrysin regime. From the x-ray picture the best indications could be obtained for choice of treatment in tuberculosis. A number of the lecturer's lantern slides illustrated the good effects of both these treatments in selected cases. In some instances both treatments had been applied to the same case—collapse therapy to the one lung and sanocrysin to the other. He also urged close co-operation between the radiologist and those engaged in the treatment of tuberculosis so that a qualitative diagnosis might be reached with the greatest sureness.

### X Rays in the Treatment of Breast Cancer

The last of the three visitors to speak was Professor HANS KESLER (Basle University) who referred to the use of x-rays after operation for cancer of the breast, he had used the method in the Basle University Clinic since 1916. He first treated cases of inoperable carcinoma then operable recurrences and metastases, and finally carried out after-treatment on operated cases. The radiation was applied as soon as possible after operation. One Sabouraud dose being given through from 1 to 3 mm of aluminium. Of twelve patients irradiated as far back as 1918, seven were

still alive in 1927 and enjoying good health, two had died of cancer, and three had succumbed to other maladies. The heaviest mortality in breast cases arose among patients with pure scirrhous, and he was inclined to endorse the prognosis of the late Dr. Hedinger, based on histological considerations, that scirrhous was the most dangerous, and medullary carcinoma the least dangerous, type. By x-ray treatment inoperable cases had been rendered operable, tumours had been mobilized, and gland metastases reduced and then removed. He believed intensive irradiation for cancer of the breast to be an error. Wintz, the inventor of that method, and other radiologists in Germany, had now returned to the use of the minimum filter. Personally Professor Iselin said he had never been a believer in intensive treatment; he had never used the "carcinoma dose," and, in fact, so far as he could see, there was no such thing.

The thanks of the Section to the three visitors from abroad were expressed by Sir PERCIVAL HARTLEY and Dr. CLIVE RIVIERE.

### WHAT IS COMPARATIVE MEDICINE?

At a meeting of the Section of Comparative Medicine of the Royal Society of Medicine, held on October 26th, Dr. O. CHAIRLOCK BRADLEY, Principal of the Royal (Dick) Veterinary College, Edinburgh, read a paper entitled "What is comparative medicine?"

The word "comparative," he said, was capable of numerous interpretations, depending on the point of view of the interpreter. It was often considered to be synonymous with veterinary medicine. In the early days of history only one or two animals came within the consideration of veterinary medicine in a pastoral country like Bithlon, in the third millennium not only sheep and cattle mattered, while in a military country like Rome the horse was of paramount importance. Nowadays, however, it concerned itself with a great variety of species, ranging from the horse to cage birds, suffering from different diseases which were not all intercommunicable and which presented different manifestations. Veterinary medicine, then, afforded ample scope for comparisons and could well claim to be recognized as comparative medicine, but it did not include man and there was no justification for the exclusion of human medicine from comparative medicine, while there was abundant warrant for regarding both human and veterinary medicine as branches of a larger medicine. Both had a similar birth and growth. Both dealt with like problems by like means. Co-operation, long existing between both, had increased remarkably in recent years. There was, therefore, no sound reason for denying to them the collective title of "comparative medicine."

Comparative medicine, however, should have an even wider and more comprehensive connotation. Medicine had been built up gradually from materials imported, and these importations were most clearly evident in the foundations. The cell theory of Schwann and Schleiden, and the discoveries of Leenwenhoek, were of fundamental importance, although neither worked initially in the interests of medicine. It was never possible to predict when and where the results of research in one branch of science would affect the problems of other branches. Moreover, no one could foresee what provinces of science might not have to be asked to assist in any particular problem. The daily work of the medical man and the veterinary surgeon was essentially analytical and as it was always easier to analyse than to synthesize, they busied themselves with the relationship of things to man, rather than their relationship to each other. Accordingly this analytical method, invaluable as it was, must be checked and controlled by as extensive a general survey as possible.

Comparative medicine contained elements contributed from widely diverse sources, the physicist, the chemist, the biologist, the pathologist, all helped to accumulate the store of linked ascertainable facts which the practitioner took for his use. Thus regarded, it was an instrument for the proper comprehension in the perspective of the problems of human and veterinary medicine.

With little reservation comparative medicine might be considered as standing to applied medicine in much the same relationship as do pure and applied science. Just as

it was impossible to say when the truths of pure science might be applied, so was it impossible to predict when the facts of comparative medicine might form part of applied medicine. The work of Pasteur at first had no semblance of being an adjunct to medicine, and it progressed long and far before it became applied to veterinary medicine, and even longer before it touched human medicine. Comparative medicine, in brief, was a storehouse, be the provenance of its contents what it might, from which human and veterinary medicine could choose such things as were of possible application, and, taking them, give.

### JAMES MACKENZIE INSTITUTE

#### *Physiology of the Stomach*

In a lecture at the James Mackenzie Institute for Clinical Research, St. Andrews, on the influence of diet upon the physiology of the stomach, Dr. JOHN BOYD ORR pointed out that in much of the earlier work on the stomach there was a tendency to limit attention too exclusively to phenomena occurring in the stomach as if it were a semi-independent organ. The work of the past few years, however, has emphasized the close relationship and interdependence of the activities of the stomach and those of the other parts of the alimentary system. A derangement of function originating in any part of the alimentary canal tends to disturb the normal activities of the stomach, and many clinical symptoms located in, or at least referred to, the stomach have their origin in other parts of the system. In discussing the function of sensation, he distinguished between hunger and appetite. The former could be correlated with the contractions of the gastric muscle; the latter, however, depended not only upon the tone of the muscle, but also upon stimuli received from sight, smell, taste, and memory. Instances were given of cases of perverted appetites in animals, and it was shown that these tended to occur on deficiency diets, and that in many cases the abnormal substance craved for was rich in the substances which were deficient in the diet. It was suggested that hunger might indicate a demand for quantity of food, and that appetite was to some extent at least, in indication of quality rather than quantity.

With regard to the function of secretion, Dr. Orr said that a review of the most modern work indicated that perverted secretion, or excess or deficiency of gastric juice, was of less importance in the etiology of disease than had been formerly supposed. He regarded movement as the function which played the most important part in the maintenance of health and the causation of disease. Recent work had shown that the former conception of the acid alkali control of the pylorus was untenable. The movements of the stomach, including those of the pylorus, were of the same nature as those of the rest of the intestine, following the law enunciated by Bayliss and Starling. The pylorus was seldom, if ever, in health completely contracted. While the general movement of the food was outward from the stomach to the intestine, there was a normal tidal flow between the duodenum and the stomach, and it was this tidal flow which regulated the degree of acidity in the latter organ. The chief factors which influenced movement were, normally, diet and the emotions. Experimental results showed that the composition of the diet had both an immediate and a remote effect upon movement, the remote effect being produced by an alteration in the circulating fluids of the body. One of the most interesting features of the results of feeding experiments with deficiency diets was not the gross disturbances in the body, but the disturbances of the function of movement in the intestine which led to lesions such as inflammation and ulceration, especially in the pyloric and caecal regions. Discussing the influence of the sympathetic nervous system on the gastro-intestinal movements, Dr. Orr expressed the opinion that emotions such as fear, anxiety, and anger, which stimulated the sympathetic, causing inhibition of movement and contraction of sphincters in the intestine, were an important factor in producing stress in the lower part of the tract, and that this was often the beginning of permanent lesions.

## Rebiefus

### THE BRIGHT CENTENARY

THE third and fourth quarterly instalments of this year's volume of the *Guy's Hospital Reports* are combined and form a Bright Centenary number containing a most interesting symposium. Professor W. S. Thayer's charming oration on Bright, which was printed in full in our issue of July 16th, appears here also illustrated by three plates of his hero at different ages. This most complete study of a great pioneer bears evidence of much research and the elaborate references constitute a valuable and most complete bibliography of Bright's published work. The actual site of the special wards called "climical" in which so much of the observation and teaching of the physicians of Guy's Hospital was carried out is described by Mr. H. L. Eison, C.B., superintendent of Guy's Hospital and its senior ophthalmic surgeon. Under the title "Chronic Bright's disease without albuminuria," used by F. A. Mahomed in his M.B. thesis at Cambridge in 1881, Dr. J. A. Ryrie argues that the whole story of high blood pressure was constructed at Guy's between 1827 and 1881 by the pathological and clinical labours of Bright, Wilks, Gull and Sutton and Mahomed. Three articles from well known authorities in Germany, France and this country—Professor Ludwig Aschoff of Freiburg on 'Disorders of the kidneys with symptoms of Bright's disease,' Professor A. Lemoigne of Paris on its outstanding syndromes, and Sir John Rose Bradford, President of the Royal College of Physicians on uræmia—admirably express the appreciation of the medical world beyond the precincts of Bright's hospital.

Professor M. S. Pembrey reviews the work of Starling and his pupils on the process of secretion in the kidney; Mr. J. H. Pfeiffer sums up the practical bearing of tests for renal efficiency pointing out that apart from the question of determining the presence or amount of renal damage the estimation of the plasma bicarbonate is more important than that of the blood urea in deciding about operation and in his 'Studies in Bright's disease,' Mr. A. A. Osman continues his observations on the value of alkalis in the treatment of Bright's disease and its prevention. The development of the kidneys is described by Dr. C. W. Nicholson, and Mr. A. Ralph Thompson discusses the association of chronic Bright's disease with obstruction in the lower urinary tract. The incidence and pathological features of nephritis in early and in late syphilis with references to the literature are considered by Dr. C. B. Dowling who illustrates the highly characteristic picture of the acute syphilitic nephritis seen in rare instances during the early stage—namely during the first year after infection—thus contrasting with the nephritis that may arise in the latent period following the secondary stage and in the tertiary phase. The surgical treatment of chronic parenchymatous nephritis by decapsulation is favourably considered by Dr. John Fawcett who prefaces his careful discussion by admitting that the surgical treatment of chronic Bright's disease might well seem to emanate from the home of lost causes, but there is not any further reference to suggest that the senior of the two older universities is really responsible for Edebohls' operation.

Dr. H. C. Cameron writes wisely on nocturnal enuresis, and Dr. F. A. Knott pleads for more frequent bacteriological examination of the urine when clinically latent or intermittent septicaemia may appear probable. Dr. E. J. Greenwood, in discussing nephritis as a result of tonsillar sepsis, remarks on the much greater frequency of this sequence than of nephritis after acute otitis media, pneumonia, and skin sepsis, and from analysis of thirty-eight cases shows that in acute nephritis due to the tonsils their removal definitely improves the outlook by diminishing the risk of recurrent attacks and of chronic nephritis, but that

when chronic nephritis has developed it is very doubtful if tonsillectomy will do any good. While admitting that there is not any mental syndrome specifically and solely related to Bright's disease Dr. R. D. Gillespie gives an account of the forms that may occur and makes some comments on the rarity of Bright's disease in the insane.

### ATHLETICS AND THE HEART

If the reader will examine the evidence carefully for himself much information may be gathered from the book on *Heart and Athletics* by Drs. Felix Detsch and Emil Kant, translated into English by Dr. Louis Wapf. The authors have had the opportunity of examining in recent years and by modern methods many athletes of all types at the heart station in Vienna, and in this volume they present an analysis of their observations. The book is diffusely and confusingly written, it is difficult at times to be sure of the precise meaning of the text and it is a pity in such a controversial subject that more attention has not been paid to the manner of expressing the conclusions. How far this is due to translation cannot be estimated, since the original German text has not been available for comparison.

In the conclusions at the end of the book it is said that the most important fact recorded is that athletics brings about changes in the heart in a not unaccountable number of cases which in the present state of our knowledge, cannot be looked upon as harmful. Stated in this form the conclusion is not justified by the evidence given, for the numerous tables show and the authors themselves admit that the majority of athletes possess absolutely normal hearts. Less objection can be taken when it is stated, as on page 117 that "the normal man bears a marked loading of his heart without any change being produced in it on the contrary the 'inferior-value' heart suffers in often increasing enlargement early, even with slight strains made upon it." In other words if the true meaning of cause and effect be borne in mind "athletics" is not a cause of cardiac enlargement. The author brings forward no convincing evidence of enlargement of the healthy heart by effort, and such evidence as is given seems rather to support the view that if a heart is enlarged as the result of exercise, then it is an unsound heart.

### THE NORMAL CHEST OF THE ADULT AND THE CHILD

*The Normal Chest of the Adult and the Child* written by Professor J. A. Myers in collaboration with five other members of the teaching staff of Minnesota University is a book whose appearance indicates the gradual advance that is being made in medical education. It represents the outcome of an attempt to teach the student something about the normal chest before confronting him with a pathological one. Many will remember the confusion of the first three months of clinical examination when we were faced with a medley of heart and lung cases, and were expected to sort out for ourselves the pathological from the normal. Interesting work it was, and stimulating to the mind but it was not good teaching. That position is now changed and both in this country and in America the student is being taught the standards of the normal chest by means of auscultation, radiography, and vital capacity measurements.

The book before us is excellently suited to those who have charge of this branch of teaching. After dealing with the anatomy and physiology of the heart and lungs it goes on to electro-cardiography and the x-ray examination of the chest to the correlation of body weight and chest measurements to the development of the thoracic organs,

*Heart and Athletics*. By Dr. Felix Detsch and Dr. Emil Kant. Translation by Louis M. Wapf. A.B. M.D. London: H. K. Lewis, 1927. (5s. 6d.) 16s. 6d. net.

*The Normal Chest of the Adult and the Child*. By J. A. Myers in collaboration with S. S. Jary White, R. E. Scammon, A. T. Ramirez, C. A. Stewart, George F. Felt. With an introduction by Elias P. Lyon. London: Baillière Tindall and Cox, 1927. (Med. 8vo. Pp. xv + 413. 14 figures.) 22s. 6d. net.

*Guy's Hospital Reports*. Vol. 7 (Vol. 7, fourth series). Nos. 3 and 4, July and October 1927. Edited by Mr. L. F. Hirst, M.D. London: The Lancet, Ltd. (Med. 8vo. Pp. 25-602. 4 plates. 2 figures. Price 4s. 6d. net. Number 25s. Annual subscription 12s. 6d. for volume of four parts including numbers 12s. 6d.)

and to the physics of percussion and auscultation. The information is fairly full, it is perhaps a pity that the erection of the heart and lungs to exercise is not more fully considered, and that the estimation of basal metabolism is not included, but no doubt the editor has sufficient reasons for restricting the book to its present limits.

### THE FLUSHINGS OF THE MENOPAUSE

In a monograph of fifty odd pages entitled *The Flushings of the Menopause*, Dr. HANNAN records his investigations and discusses possible lines of treatment. Its chief merit is that it is based on the personal observation of 131 women, of whom 73.3 per cent complained of some degree of flushing, and 26.7 per cent did not. The distribution, character, duration, and frequency of the flushings are noted, together with any symptoms associated with or immediately preceding or succeeding the flushing.

Flushing is regarded as a "vasomotor crisis" and observations are given, unfortunately only in four patients, on the changes in blood pressure and pulse rate before, during, and after flushing, and an attempt is made to correlate the intensity of the crisis with the age of the patient, the character of the menstrual changes, and the psychological condition of the patient at the menopause.

The material at the author's disposal is much too small for anything definite regarding the nature and treatment of menopausal symptoms to be based on it, and severely warrants the conclusions summarized at the end of the monograph. His work will, however, be found suggestive and useful.

### A COMMEMORATIVE VOLUME

VOLUME XVIII of the Italian archives of surgery is dedicated to Professor Raffaele Bastirrelli in celebration of his having attained the twenty-fifth year of his professorship, and it contains nearly one hundred articles of surgical and pathological interest, written by colleagues and admirers in his own country and abroad. A few only of the contributions can be referred to here. Professor Arcangeli writes on "osteomielitis," distinguishing the disease from senile osteoporosis and from the so-called starvation osteomielitis. True osteomielitis he holds to be an infective disease caused by the diplococcus discovered by Mopingo in 1890. Its infective nature is further shown by its frequency in some localities and its rarity in others, by its appearance in the form of epidemics, and by the frequent occurrence of several cases in the same house. Osteomielitic patients, he states, mostly have rickety children or have lived with osteomielitic or rickety children. The infection is supposed to be transmitted through the urine and feces, and one of the reasons why women are especially liable to the disease is said to be their frequent contact with rickety children. Fehling's theory that the disease is caused by disordered ovarian function and curable by ovariectomy is rejected by Arcangeli, who considers that any effects that follow the operation are due to the chloroform inhalation rather than the operation itself. According to the author, true osteomielitis can be almost always cured by inhalation of chloroform. It is necessary that the necrosis induced should be profound, as if for a major operation, and that it should be continued for three-quarters of an hour or an hour. Arcangeli has treated 150 patients by this means with almost uniform success. Professor Leucbe contributes a paper on section of the ram communicans for relief of painful affections of the extremities, reference being made chiefly to painful stumps and to diffuse osteomyelitis. In Raynaud's disease and erythromyalgia, he considers that percutaneous sympathectomy is successful in 85 per cent of cases having occurred in various forms of juvenile arteritis. In the treatment of osteomyelitis, while in scleroderma percutaneous sympathectomy combined with sympathectomy gives the best results, he regards sympathectomy as the best method.

With little reservation considered as standing to the same relationship as do pure

of the brachial plexus as an essential part of the treatment, combined with section of the sympathetic trunk above the inferior cervical ganglion and of the ram communicans of the vertebral nerve. With regard to painful stumps, he distinguishes two types. In one the vasomotor disturbance is peripheral and objective (coldness, cyanosis, trophic changes) and the pain is supportable, such cases are generally cured by percutaneous sympathectomy. In the second type the pain is intolerable, diffuse, radiating further with the lapse of time, and in form of such cases congestion of the corresponding region of the cord was observed. No peripheral operation of any kind gives permanent relief in this type, although division of the posterior roots may give a partial or temporary relief. Sympathectomy, on the other hand, which was performed in four cases, has given immediate and complete relief, persisting for seventeen, five, four, and two months respectively, and the author regards it as the operation of choice. Sympathectomy was found to be equally satisfactory in those distressing cases in which severe neuritis follows some insignificant traumatism—the so-called ascending traumatic neuritis. These cases are at present held to be incurable, but Leucbe found that sympathectomy gave complete and apparently permanent relief in three cases. Sir Berkeley Moynihan contributes a valuable article on perforating gastric and duodenal ulcers, their diagnosis and treatment.

### MEASLES

In the preface to their book on measles, Drs. ROBERT DUBREUIL and PIERRE JOUHANOV are careful to state that it is not to be an exhaustive study of measles, but merely an exposition of the facts connected with the epidemiology, immunology, and prophylaxis of the disease. Both writers, particularly Dr. Debré, are well fitted to write such a work, as they have for some years taken an active part in the campaign against measles and, as will be seen from the bibliography to the volume, have made several contributions to the literature of the subject.

The book is divided into three parts, dealing with the epidemiology, immunology, and prophylaxis of measles respectively. In the first part the writers discuss the mortality from measles, giving tables showing the mortality in ten different European countries, the factors of mortality such as age, sex, previous health, epidemic constitution and environment, and the social factors in the high mortality from the diseases in the working classes. The second part, which deals with immunology, contains two chapters, the first of which is concerned with susceptibility to measles during and after the first year, special attention being paid to the subject of congenital measles. In the next chapter an account is given of the contagiousness of measles at various stages of its course and of the immunities contained in the blood. The third part, which forms the most important section of the book, deals with prophylaxis. The writers begin with the study of general methods, and then go on to discuss prophylaxis by convalescent serum, or the whole blood or serum of those who have had measles some time previously, such as the parents and, finally, active immunization against measles by modification of a method first introduced by Francis Home in 1758. An extensive bibliography is appended.

The book contains an admirably lucid exposition of the recent work on the aspects of measles described. We must, however, take the writers to task for giving to an imaginary "Mme. en Angleterre" (p. 220) the credit for testifying to the prophylactic value of convalescent serum which, to judge from the dearth of literature, has so far not been employed in this country in the prophylaxis of measles.

### PATRICK GEDDES AND TOWN PLANNING

MANY members of the British Medical Association attended the Annual Meeting in Edinburgh last July and have noticed a tall building nearly at the top of Castle Hill, upon which is mounted an observatory. In a book

by Patrick Geddes, *La Nouvelle* (Paris, 1926), the author, who is a member of the Académie des Sciences, discusses the importance of town planning in the prevention of disease. He refers to the observatory on Castle Hill as a symbol of the need for a new approach to town planning, one that takes into account the health of the population. He also mentions the work of the British Medical Association in this field.

By John H. Hannan, M.A., M.D., F.R.S., F.R.C.P., F.R.C.S., F.R.C.O., F.R.C.S.D., F.R.C.S.(E), F.R.C.S.(G), F.R.C.S.(I), F.R.C.S.(N), F.R.C.S.(S), F.R.C.S.(T), F.R.C.S.(U), F.R.C.S.(V), F.R.C.S.(W), F.R.C.S.(X), F.R.C.S.(Y), F.R.C.S.(Z). London: Tindall and Cox, 1927. (5s. 6d.)

entitled *The Interpreter, Geddes*, written by Miss Amelia Duffries, we learn that this tower was once the habitation and laboratory of Patrick Geddes, sometime professor of botany at St. Andrews University, and now professor of sociology and civics at Bombay. The book under review purports to be a life of Geddes and an exposition of the principles for which he lives and works.

Geddes has many sides. He was a biologist first and with Professor Arthur Thomson wrote some works on the evolution of sex that are well known and much read. But he ranges outside the strict limits of theory into the fields of practical sociology into statistics, economics, the dramatization of history, war, civics, the vexed coal crisis, and, most of all, into town planning. And who shall say that these divergences are outside the field of biology? Geddes is without doubt an eccentric genius, geniuses are often eccentric, and perhaps they are entitled to be so for they are outside law and a law unto themselves. But alas! his biographer has caught too much of his eccentricity, so that it is with difficulty that the reader can discover from her book any clear picture of her revered master, she eludes for him that he is "The Interpreter," but she fails to be an interpreter of him. Nevertheless, the book is one of interest. Town planning is certainly the chief love of Geddes, and in that field he has done some remarkable work. The design for the University of Jerusalem for which he and Morris were responsible, and of which there is an illustration in this book would alone give him claim to distinction. But he has served in wider field, notably in India, where he prepared many reports on town planning.

Perhaps one of the most amusing parts of the book is the story of the town planning exhibition in Ghent in 1913. Geddes took part. The visitor sought out his exhibit on the eve of the opening. There was found,

the gallery of the vast German Pavilion magnificently arranged. Every photograph was a fine one, every plan splendidly drawn and each exhibit was not only well framed and glazed but in good taste. Underneath each was a clearly printed label in gold and black, the whole was well hung and the wall covering artistic. Thus the gallery presented a unity and harmony which heightened the efficiency manifest throughout. Guardians in German uniform stood at each end of the building who were able to reply intelligently to all my questions.

But no one knew where was Geddes's show except these German officials. When at length the right place was discovered

I stumbled over scaffolding and fell into a litter of maps, plans and prints scattered over the floor. Around was a vast gallery partitioned into smaller rooms of different sizes, papered with yellow casing on which were roughly pinned plans, photographs and incomprehensible-looking diagrams. In every room masses of material were scattered on the floor with endless piles of apparently disordered notes among them some realistically horrible representations of war. Hearing voices I ventured further and there on his knees working in shirt sleeves and at high pressure—was the slim, agile, bearded figure of the master. Yet Geddes, received the International Award, and not the Germans.

The book has a foreword by Rabindranath Tagore and a preface by Lewis Mumford, who knows and tells what Geddes has done, and a very interesting introduction by the late Israel Zangwill which ends with the words: "We no citizens of no earthly city. That is not to say we should be content to be citizens of mean cities."

#### A GUIDE TO BEGINNERS IN GENERAL PRACTICE

To justify his choice of "career" the general practitioner must acquire speedily some business knowledge, the faculty for orderly arrangement of his life, and an extensive and varied acquaintance with human psychology, especially of the human sick. No teaching school has ever yet considered it part of its duties to instruct its students in these essentials, probably because teaching staffs know nothing of the matter. Dr. W. S. SYKES, though comparatively young in practice, endeavours to enlighten the beginner by his *Manual of General Medical Practice*.

*The Interpreter, Geddes, the Man and His Work*. By Amelia Duffries. London: George Routledge and Sons Ltd. 1927. (Demy 8vo. Pp. xiii + 335. Illustrated. 16s. 6d. net.)  
*Manual of General Medical Practice*. By W. Stanley Sykes, M.A. M.B. B.Ch. Cantab. D.I.H. Lond. etc. London: H. K. Lewis and Co. Ltd. 1927. (Cr. 8vo. Pp. xii + 267. 7s. 6d. net.)

Dr. Sykes writes in a pleasant and readable style, evidently he takes the trouble, so often neglected by general practitioners, of keeping records of his practice, and he can be quite interested in analysing his results, and he can be quite forcible in defending the honour of the general practitioner. When he went into practice he had no idea what influence was like. Osler's *Medicine* had given him three and a half pages, which he found unsatisfactory about influenza to forty-six about typhoid. Yet he has had to treat 112 cases of the former disease for every enteric case. He disagrees with Osler that the thermometer is the most trustworthy guide in the diagnosis of appendicitis and relies on a rising pulse rate with increasing toxicæmia. Dr. Sykes resents the tendency of the official to attribute puerperal fever to infection by the doctor, and he challenges highly placed medical officials to polish up their knowledge of midwifery and conduct a series of confinements themselves. He considers that the Royal Commission on Venereal Diseases estimated the number of those infected with syphilis far too high, and that more reliance can be placed on the figures for unselected fragments of the population, such as form the clientele of a general practice, than those derived from bodies of lunatics, convicts, or peccolized groups. Thus amongst 2,250 individuals in his practice the prevalence of syphilis was 0.22 per cent. instead of 10 per cent. He admits that his figure is too small but he points out that a proportion of 10 per cent. would mean that for every case recognized he had overlooked forty-nine. Dr. Sykes humbly submits that his powers of diagnosis are not as bad as that. The experience of most general practitioners would probably support his views.

While much of Dr. Sykes's book will appear mere truism to established practitioners, to the student starting in practice its many suggestions should be invaluable.

#### NOTES ON BOOKS

A new textbook of clinical ophthalmology has been written by two French doctors, Messrs. JACQUES DUVERNEAU and ARSCOLA. For some time over the first half the book is arranged on the customary systematic plan, but for the rest it is composed of a series of monographs of a distinctly attractive and illuminating order. There are chapters on the innervation of the eye and its disorders on congenital anomalies on tumours and pseudotumours on the pathology of the eye and its relation to general pathology, on ocular medication and general therapeutics on injuries to the eye and their medico-legal aspects and the determination of percentages of invalidity. The book is well written and well printed. The arrangement of the paragraphing is good, there are ample spacing so that the eye of the reader is not wearied with a never-ending succession of unrelieved grey pages. But the illustrations are poor, judged by our standards, they are few in number and the representations or tenuous drawings are such as might be considered likely to deter anyone from attempting to see their originals. The volume is of cumbersome shape—somewhat like Bradshaw's railway guide squat and heavy.

SIR W. ARBUTHNOT JAYE has written a little book with the title *Secrets of Good Health*. It appears for the most part to be a collection of articles which have appeared in the *Daily Mail* on matters of health interest. The book deals with a variety of topics in a brief and vigorous manner. The author claims that "These hints will explain in simple non-technical language how and why the human organism benefits or suffers from the various physical influences to which it is subjected under the complicated conditions of modern life and diet." Much attention is given to food and food values and notes by other writers on these subjects are included. Many of the opinions expressed are individual, but this adds emphasis to the writing. One suggestion seems to us somewhat surprising. The author very properly animadvertes upon the lack of sufficient lavatory accommodation especially for women and upon the ill effects of constipation. But he appears to be altogether dissatisfied with one good evacuation of the bowels a day and suggests that in the natural state defecation would follow each meal and that this habit should be cultivated. If suitable foods are eaten the bowel evacuates a quantity of

*Hygiène*. Par A. ROCHON DUVERNEAU et ARSCOLA. Paris: 1927. (Demy 8vo. Pp. 128. 16s. net.)

London  
viii + 152.

material after each meal, proportionate in bulk to the amount of food taken." There may be persons to whom such a sequence of events would prove an advantage, but if the proposition thus stated be universally true, then there must be many who will say "Let me eat unsuitable foods, and leave me to my one good action a day."

The story of the naval operations in the South Atlantic and Pacific in 1914, as told by Lieutenant Commander JOHN IRVING, is a thrilling romance of the sea.<sup>11</sup> Not that it is the author's intention to be picturesque. On the contrary, he writes seriously, with the apparent, though not expressly stated, object of bringing into relief certain fundamental requirements in naval armament, and the age-old chivalry of the sea that ceased with the advent of the submarine. The demands and estimates of the navy were often, we are told, the shuttlecock of political opportunism, and invariably suffered. Lack of cruisers, intensified by their withdrawal in subordination to military whims of the moment—to form escorts for expeditions set on foot prematurely for territorial acquisitions, exposed our maritime trade—our vital and most vulnerable point—to attack by the enemy. In arriving out the task of freeing the trade routes, met by sea, from this menace Craddock's heterogeneous and inferior squadron was sent from the South Atlantic, by "a stupendous error of the Admiralty," to oppose the homogeneous and formidable squadron of von Spee in the Pacific, and met its fate gallantly off Coronel. Then the wheel of fortune turned, and von Spee's squadron, on entering the Atlantic, met its fate, equally gallantly, off the Falklands. The chivalry of the sea was upheld by both. In the author's narrative of the latter battle an incident, reminiscent of one in the history of the Peninsula war, is related. "As though to bring a breath of peace and tranquillity to a scene of blood, a full rigged ship was observed to pass down the lines with her sails full and bellying to the slight breeze. What she was doing there no one knew." In this battle it comes as a surprise to be told that the British casualties were only ten killed and fifteen wounded, while the German losses are estimated at 2,263.

Dr R. G. COCHRANE, medical adviser to the Mission for Leprosy has prepared a pamphlet on the symptoms, diagnosis, and treatment of leprosy for the use of those who have had no opportunity for special study of this disease. The pamphlet is clearly written and the subject is approached from the practical standpoint, so that it can be strongly recommended to those who desire a short and up to date summary. It can be obtained from the Mission for Leprosy, 33, Henrietta Street, W.C.2. On August 27th (p. 362) we referred to a recent pamphlet by Dr Cochrane entitled *Leprosy in India a Survey*.

The anonymous little book entitled *The Invert and His Social Adjustment*<sup>12</sup> is the work of a cultivated layman, himself the victim of the anomaly on which he writes. The book is intended, as Mr R. H. HOWLESS says in the introduction, for two classes of readers—namely for those who are themselves invert, to whom the writer gives excellent advice, and also for the average man who has mistaken views about the nature of sexual inversion. The work is an interesting human document and well fulfils the purpose for which it was written.

<sup>11</sup> *Coronel and the Falklands*. By John Irving, Lieutenant Commander R.N. (ret.) London: A. M. Philipps, Ltd. 1927. (Gr. 8vo, pp. 247 illus. bound 6s net.)

<sup>12</sup> *The Invert and His Social Adjustment*. By Anomaly. With an introduction by Robert H. Howless, M.A., Ph.D. London: Baillière Tindall and Cox. 1927. (Cup. 8vo, pp. xxi + 160. 3s 6d net.)

## PREPARATIONS AND APPLIANCES

CLAMPS FOR GASTRECTOMY AND GASTRO-ENTEROSTOMY  
Mr C. W. CATHCART has devised two clamps for abdominal surgery, which he finds are very satisfactory. He writes:

Both clamps are of similar construction. Each consists of parallel steel bars approximated by a screw at each end. This mechanism allows a delicate adjustment of pressure, which can be increased at will to a crushing force. The advantage of having the pressure thus under control is especially important in the operation of gastro-enterostomy. The ordinary type of forceps, which moves on a pivot, has been found to injure the gastric mucous membrane by unequal pressure at certain parts.

1. *The Gastrectomy Clamp*—This consists of two strong steel blades shaped as shown in the illustration. They are eight inches long, and a quarter of an inch broad where their surfaces meet. The lower blade (that is on the reader's right) has fixed to it a short rod "A," which is tipped with a screw. At the other end of this blade there is an oval hole into which the oval head of rod "B" fits, "B" is therefore detachable, but cannot rotate in its socket. The upper blade (that is on the reader's left) has a hole at each end which allows the rods,

"A" and "B" to pass easily through. Each rod is supplied with a large screw nut by which the blades can be pressed together.

*Mode of Use*—After the stomach has been prepared for resection "B" is removed and the nut of "A" loosened. The free ends of the blades are passed above and below the stomach at the site chosen for resection. "B" is then inserted through the holes in the blades, and its nut is fitted on to it. The blades are then pressed together by screwing down the nuts, which are turned from time to time as the tissues are compressed. When no further pressure can be made the nuts are loosened and the blades allowed to separate. The clamp is then used as a tourniquet as follows. It is moved about 1½ or 2 inches nearer the fundus of the stomach, and the nuts are carefully screwed down till the stomach is compressed sufficiently to prevent hemorrhage or the escape of gastric contents, and no more. The crushed portion of the stomach is then divided and sewn up. "B" is then removed, and the clamp with drawn. The parts beyond the affected portion of the stomach or duodenum are afterwards dealt with, and the operation is completed as may be required.

### 2. The Gastro-enterostomy Clamp

This is a lighter form of the gastrectomy clamp. The blades are much lighter, because they are needed only for holding the required fold of stomach wall. They are grooved longitudinally. At the proximal end of the blade, near "A," a small block of steel is attached. It is pierced with six small holes, tipped with a screw, about a quarter of an inch apart. The intestinal forceps (3) which are required for this clamp are of the usual light type with the following addition. A small block of steel is fastened under one of the blades just beyond the pivot. To this two small pins are attached, projecting to the left, one is plain, and the other, "C," is screwed to fit the holes on the clamp.

*Mode of Use*—Having exposed the part of the stomach wall which is to be connected with the duodenum, pass a right needle (round point) with a thick strand of silk or catgut into the muscular coat of the stomach at each end of the intended line of incision into the stomach. Draw each thread through the wall, leaving about four inches of double thread free. Knot the ends together, and cut off the rest along with the needle. This leaves a loop of catgut at each end of the intended line of incision. Open the blades of the clamp and gently draw the selected part of the stomach wall between them by means of the catgut loops. Then approximate the blades to hold the fold securely and no more. Now grasp the selected portion of the jejunum lightly with the intestinal forceps and lay the forceps alongside of the clamp which holds the stomach. Adjust the forceps to the clamp and fix the two together by screwing the rod with the milled head, "C," into the hole which most suitably adapts the intestine to the stomach. Remove the catgut loops and proceed with the gastro-intestinal anastomosis. When the suturing is complete release the intestinal forceps, first from the clamp, and then from the intestine. Lastly, having screwed off the nut, remove "B," and withdraw the blades of the clamp.

The makers are Messrs Smith, Hurford and Drysdale, 21, Lauriston Place, Edinburgh.

### ERGOTOXINE

We have received from Messrs Burroughs Wellcome and Co. a sample of ergotoxine ethanesulphonate. This is a new preparation of the alkaloid ergotoxine, which is one of the principal alkaloids of ergot. Ergotoxine was introduced by the Burroughs Wellcome and Co. many years ago, and sold by them as ergotoxine phosphate. The recent discovery of the allied alkaloid ergotamine has stimulated interest in their principles of ergot. Ergotamine and ergotoxine differ in their chemical formula but appear to have the same qualitative pharmacological action. The evidence available suggests that the intensity of their actions is also similar. It will be of interest to see if further research reveals any difference in the action of these alkaloids. It is satisfactory that the alkaloid ergotoxine is now available in a form which, the makers state, has various advantages over previous preparations.

## Notae et Vetera.

### A SIXTEENTH CENTURY LONDON PHYSICIAN'S BOND, 1587

I was fortunate in acquiring this document it among a bundle of ancient deeds, most of which were of early date and none or then of a later date than that of Queen Elizabeth. The text is as follows:

This Indenture made the thirde day of Marche in the eighte and twentieth yere of the reigne of Our Sovereigne Lady Elizabeth by the grace of God Queene of England France and Irland Defendor of the fau he etc Betwene William deLaune of London Doctor in phisic on thone partie And Adam Rayneshave Citizen and Carpenter of London on thother partie Witnes eth that whereas the said Adam Rayne have by one recognizance of the nature of a statute staple bearing date the day of the date of this presents Taken and acknowledged before the righte honorable Sr. Christopher Wraye Knight Lorde Cheife Justice of the Queene's Mye ty Court comorle called the Kings Benche at Westminster to holde and standeth bounde unto the said William deLaune in the somme of Thre hundred pounds of lawfull money of England Payable as by the same recognizance more fully at ludge doth and may appere. Nevertheles the said William deLaune for him his heires executors administrators and assigns and for every of them doth covenant and grante to and with the said Adam Rayneshave his heires executors administrators and assigns and every of them by this presents That if the said Adam Rayneshave his heires executors administrators or assigns or any of them do and shall well and truly paye or cause to be paid to the said William deLaune his executors administrators or assigns At or within the nor dwelling house of the said William deLaune called the signe of the three starres situate ad beinge within the precincts of the Blacke friers nere Ludgate in London the somme of one hundredth and fower score poundes of lawfull money of England in manner and forme followinge (that is to say) On the fourth day of Marche which shalle in the yere of our Lorde God One thousand fyve hundredth fyve score and sixe fiftene pounds and on the fourth day of Marche that next immediately followinge which shalle in the yere of our Lorde God one thousand fyve hundredth fyve score and seven one hundredth thre score and fyve poundes THAT THEN the said recognizance shalbe clerelie voided and of none effecte AND IF defenite lill happen to be made in payement of the said some of one hundredth and fower score pound or any parte or parcell thereof contrary to thorder forme and place aforesaidclered. THAT THEN the said Adam Rayne have for him his heires executors administrators and assigns and for every of them doth covenant and grante to and with the said William de Laune his heires administrators executors and assigns by this presents That the said recognizance shal stande abyde and remaine in full strength and vertue AND FURTHER the said William de Laune for him his heires executors administrators and assigns doth covenant and grante to and with the said Adam Rayneshave his heires executors administrators and assigns by this presents That he the said William de Laune his executors administrators or assigns immediately after that full payment shalbe had and made of the said somme of £180 in forme aforesaid according to the true intent and meaninge of this presents shall and will upon the lawfull request or demande of the said Adam Rayneshave his executors administrators or assigns therefore to be made not only deliver or cause to be delivered to the said Adam Rayneshave his executors administrators or assigns At or within the forsaide nor dwelling house of the said William de Laune the forsaide recognizance or statute staple to thintent to be cancelled and made void But also at the costs and charges of the said Adam Rayneshave his executors or assigns shill and will At or in the office of the clerke of the staple for the tyme beinge to be holden and kepte in London give his or thers consent that a vacat or entree shal or may be there entered (if nede shall so require) As by the said Adam Rayneshave his executors or assigns or by his or here learned counsell shalbe reasonably devised whereby it may there appere that the same recognizance or statute staple is discharged and made void In witness whereof the parties first above named to these indentures sounderly have set their seales the day ad yere above written 1587

The seal is missing, but on the tag is written, in two hand "Sigillatum et deliberatum in presencia Roberti Balere feltmker et mei Willelmi Sesche (?) scrivener"

An account of William de Laune will be found in Munk's *Roll of the Royal College of Physicians* (second edition, vol 1 p 84) From this source we learn that he was buried at St Anne's, Blackfriars, on February 19th, 1610

DeLaune's son, Gideon was a prominent man in the early days of the Apothecaries' Society, and he had other children as appears from a study of his will, an abstract of which is as follows:

(P.C.C. Wood 23) William deLaune preacher of the word of God and Physician 27th November 1610.

To be buried here unto my late decess wife if it be possible In form of ale to Gideon deLaune my eldest sonne all my messages lundes etc (except what I give to my sonne Paule deLaune) in present called the blackeffriers nere Ludgate of London which I late purchased of Sr William More and the said Gideon in 6 month to pay the following—Poore of frenche church in Londo £4 Poore of blackeffriers and the churches of Norwich and deepe to every one of them 20/ [this probably means 20/ to each place]. A poore kindred beyond the sea £5 to be admitted by my son Nathaniel deLaune Sister in law Mary DeLoges widow of Cornelius Tance [? Tance] £3 Sonne Paule for the good service he hath done me the new house which I built with the greates court and the house of office therein and also one of the chambers which he shall choe ready furnished and also the Apothecaries stuffe and furniture in the said new house—paying unto Gideon deLaune his eldest brother £50 Said sonne Paule deLaune these £50 mentioned in a bond under the names of Mr Burr Mr Hartley and Mr Boulton as also my silver guilt pott of a pynle for a remembrance Abraham deLaune sonne and heire to said Gideon deLaune the great silver selfe seller Perdue of goods as of the £650 which arise of the sale of my houses canell to my sons eldest son Gideon, and sonne Peter Nathaniel, and Paule and to Henry deLaune sonne and heire to Leese my sonne decessed who for his marriage received £100 And to my daughters Sara Ester and Elizabeth As for my sonne Isaac Peter Chamberlen my will is he repaire the entree of my house wherem he now dwelleth as it was when he first entered as he ought to be judgement of honest men before he receive any benefitt And since my daughters have had more than my sonnes a well at their marriages as at their mother's decess he he in maners, each sonne to have £5 extra Executors son Gideon deLaune and Nathaniel Mary my son in law And if Gideon refuses to execute then his legacies to my son Peter and as he refuse then to my son Nathaniel and if he refuse then to my son Paule In which case I will only £150 to son Gideon Witses Rob Andrews Martin Broome Roger Langton

The will was proved on March 12th 1610 (O.S.) and administration was granted to Gideon de Laune and Nathaniel Mary The deceased is spoken of as of the "parish St Anne in le Blackfriars London"

From Venn's *Alumni Cantabrigie* we learn that Peter was of Peterhouse D.D. and Pastor of the French congregation at Norwich in 1647 Paule was of Emmanuel, and an account of him will be found in Munk's *Roll* (vol 1, p 170) Abraham and Henry de Laune both figure in Venn's book, the former was of Emmanuel College and died in January, 1637/38 The latter was of Cnus College, a son of Isaac de Laune, M.D. a Frenchman he was educated at a school in Norwich (Pedigree in *Tribulation* of London, 1634) There was evidently a Norfolk connexion about this family and I regret that I have had no opportunity of consulting the history of that county

It is satisfactory to find that son Gideon did not renounce probate, let us hope also that the recalcitrant son-in-law made good the defect in the 'entree of his house' Can he have been related to the famous Peter Chamberlen? I like to think that 'sonne Paule' got "the new house," possibly that of the 'three starres' mentioned in the bond.

I am indebted to Mr John Gibbons for the abstract of the will The original deed has been deposited in the library of the Royal Society of Medicine

R. R. JAMES

## THE WATERS OF BATH.

## RECONSTRUCTION OF THE OLD ROYAL BATHS

THE OLD ROYAL BATHS

WHEN the British Medical Association held its memorable Annual Meeting at Bath in 1925, the small bathing establishment in Hot Bath Street, which was designed by John Wood the younger and has long been known as the Old Royal Baths, was undergoing reconstruction as a special block for Plombieres douches and for "large pool" treatment by re-educative exercises. It has now been finished and is ready for use. In adapting this building to modern balneological needs every care has been taken by Mr Alfred J Taylor, architect to the baths committee, to preserve Wood's ingenious planning and the many agreeable old features that give the characteristic "Bath flavour" of the eighteenth century.

The main lines and the façade of the 1777 building have been retained and freed from some later excrescences. In the centre of the block is the large pool, supplied direct from the neighbouring thermal spring, and equipped for the under-water treatment of spastic and flaccid paralyses by voluntary and controlled exercises, a method which has been in use at Bath on a smaller scale in the Cross Bath for some time past. The object is to facilitate active and passive movements in a medium which supports the limbs, relieves muscular spasm, and eases pain. For this purpose an ample supply of hot water is essential.

John Wood's beautiful little pool bath has thus been carefully restored, the only change in its architectural features being the addition of a glass roof, which in favourable weather can be opened to the sky. A lifting and travelling apparatus (shown in our illustration) has been installed for conveying helpless patients from the dressing room to the hot mineral water bath, supported by slings. There are also submerged parallel bars to assist patients in the voluntary walking exercises which form an important part of the re-education treatment.

Behind the pool are six suites of rooms admirably equipped for the Plombieres intestinal lavage and Troch douche treatments. The increasing employment of the Plombieres method at Bath, at first for colitis, and now also in rheumatic diseases, has called for the provision of more and more accommodation and the training of a staff of expert attendants. Concentration of this method of treatment in one building, specially designed and fitted for the purpose, should prove a considerable advantage, and incidentally it releases some good rooms in the Royal Baths for vapour treatment.

The reopening of the Old Royal Baths, on Saturday, October 22nd, coincided with the annual meeting of the British Orthopaedic Association at Bristol, and a large party of orthopaedic surgeons from all parts of the country travelled from Bristol to Bath to inspect the new bathing

equipment and the orthopaedic hospital at Coombe Park in connexion with the Royal United Hospital. At noon the visitors assembled in the Pump Room, and after a welcome by Mr John Hatton, director of the hot mineral baths, Dr R G Gordon briefly explained the purpose of this, the latest addition to the baths of Bath, and the indications for the hot pool treatments. Parties were then shown over the establishment by Dr Gordon, Mr W G Mumford, Dr Vincent Cortes, and Dr Charles Cuid, and demonstrations of the various methods were given.

The visitors were entertained to luncheon in the banquetting chamber of the Guildhall as the guests of the mayor, Alderman Cedric Chivers, who, to the regret of all, was unable to receive them in person owing to illness. In his absence the chair was taken by the mayoress, Madame Sarah Grand, supported by the deputy mayor. In proposing the health of the visitors the mayoress referred to Alderman Chivers's whole-hearted interest in orthopaedics

and his work for the hospitals in Coombe Park. Mr H A T Frimbank, president of the British Orthopaedic Association, in his reply, recalled the long history of Bath, with its world-famous springs and its great name for hospitality, and welcomed the presence that day of Dr F G Thomson, whom so many of them missed two years ago when illness prevented him from presiding over the Bath meeting of the British Medical Association. They were also pleased to have among them their colleague, Mr Walter Mumford, who had deputized so admirably for Dr Thomson on that

occasion. Mr Frimbank undertook to send a telegram of good wishes to Alderman Chivers, and in proposing the health of the mayoress spoke of Madame Sarah Grand's deep concern for the welfare of crippled children. The proceedings ended with a congratulatory speech on behalf of the French sprys by Dr Chesneau of Aix-les-Bains.

The new extension of the hot mineral baths was formally opened later in the afternoon by Councillor C H Hader, deputy mayor and chairman of the baths committee, who said that with this second reconstruction of the Old Royal Baths—150 years after the first reconstruction by John Wood the younger—the modernised Bathing Establishment of Bath might be considered complete. In declaring the building open he acknowledged ever warmly the interest shown by the local medical profession in the improvements that had been carried out, and their constant co-operation in promoting the great work of Bath as a centre of healing.

It is always pleasant to revisit Bath at any time of the year, but particularly on an occasion such as this, when the old city gives further proof of its ability to keep up with the ever-growing demands of medical science. The reconstruction of the Old Royal Baths provides much needed additional accommodation for the modern methods of treatment, and preserves a delightful piece of Georgian architecture.

RE-EDUCATIVE TREATMENT IN THE HOT BATH

# British Medical Journal.

SATURDAY, OCTOBER 29TH, 1927

## PREVENTION AND PERFECTION

THE problems dealt with by Dr James Whitley, county medical officer of health for Salop in his presidential address before the Society of Medical Officers of Health a week ago are of very great moment. The fundamental questions raised are the same as the more important of those discussed by Sir Robert Philip, the President of the British Medical Association in his address at Edinburgh in July last. That address was entitled "The strategic front of medicine to-day" and in commenting upon it in a leading article (July 23rd, 1927, p. 138) we ventured to describe the objectives to be attained from that front as prevention and perfection and as we then said each of these objectives is being more and more recognized and insisted upon in our time. That the president of the Society of Medical Officers of Health should have made them in effect the keynote of his address to his fellow members of the public health service at the inauguration of his new office is further evidence of this recognition and emphasis.

Preventive medicine is by no means the concern of the public health service alone. It is the study and the work of the whole medical profession. Private practitioners and public health officers alike are pressing beyond the mere recognition and relief of unhealthy conditions whether in the individual or in the community which was for so long their main business and still remains a great part of it to the wider and more satisfying aim of preventing such conditions from arising. Beyond even this step they are beginning to contemplate yet another wider and more satisfying still. With increasing purpose as Sir Robert Philip said the doctor, whatever be the exact sphere of his professional work has his mind and eye fixed on perfect on of form and function as the ultimate goal. We have ourselves more than once pointed out that health is not the mere absence of disease but the complete development of body and mind—indeed of the whole personality—to the full extent of whatever powers they possess.

There is a long way to go to these objectives. It is the more important as Dr Whitley insists that the right road should be taken and that we should not be led by a false route or wander down too devious paths. He suggests quite justly that medical officers of health should be able to take a broader view of health problems than persons engaged in one section of health work only and yet that they have not always accepted help from the best sources and have not always accurately judged the relative values of the different branches of public health work. It is quite possible, he says, for certain measures to save individual lives or protect individuals from grave ailments and yet the complete result to the nation may be bad. He even raises the doubt which is not a new one and goes deep in this matter whether the two objectives may not be incompatible—whether the successful prevention of disease may not indirectly and in the long run militate against the perfect health and development of those who escape it. Certain it is—and this may be regarded as Dr Whitley's main point—that if disease is not prevented in the right way and by the wisest means such a doubt becomes a probability.

Death is in the end, unavoidable and its mere postponement, which has hitherto been acclaimed as the main triumph of preventive and public health work, does not of itself produce a more healthy community. Indeed, other things being unchanged the result must be the opposite of this. Neither to the individual nor to the community is the postponement of death a certain benefit. It is no more certain that even a successful warfare waged against a particular scourge must necessarily result in producing by itself, a healthier race. Nor would the immunization of a whole people against a particular disease germ or against all such germs guarantee a greater perfection of national or human development if other conditions of heredity and environment remained unchanged. Yet doctors will continue to strive for the postponement or death for the elimination of tuberculosis of cancer of venereal disease and will protect the individual against the effects of disease-producing microbes by whatever means they can and any triumph they may have will be those of preventive medicine. The true means for relieving both the objectives, perfection as well as prevention, remain and must be put in their proper place. It is the removal of the causes of ill health and poor development that has to be sought and not the mere prevention of some of the effects of some of those causes. Wise behaviour is not only better than arsenobenzol but better than packets. Measures which lead to cure in making to rid of improvement in environment, good housing and good feeding both in infancy and later to reduction in personal domestic and public hygiene as well as in other matters are the only certainly efficient we possess in this campaign though others may win a battle or cause the fall of a redoubtable citadel.

Prevention of disease may some day be achieved, perfection of health never. In judging our results therefore we must beware of fallacies, especially of two which may be called the fallacy of the average and the fallacy of the physical. Curiously enough there is a passage in Dr Whitley's address which illustrates both. Past a certain age, he says but probably averaging about 60 life is no longer a national asset but a national burden. This general truth is not vitiated by the fact that many men over 60 or 70 years of age have done work of extraordinary value. It is otherwise the lethal chamber is indicated for all over 60. It is a complete fallacy to regard the exceptional merely as a contribution to the average, and not to give it its own sometimes enormous value over and above such contribution. It is a fallacy too even when calculating purely economic values to consider only physical well-being. True all-round perfection is what is aimed at. But in placing our imperfect results in the health balance we must weigh up what may go along with a feeble physique, a powerful and well-poised mind, and much something more than both of these in the personality which may be more enduring than either.

## CLINICS FOR CHRONIC RHEUMATISM

THE successful treatment of the various forms of chronic rheumatism in insured persons is very difficult. The prevalence of these complaints apparently an increasing prevalence—among the industrial classes, the grave impairment of industrial efficiency thereby caused and the urgent need for taking some further action to meet this situation have been fully recognized during the last few years. A number of conferences have considered the subject in most of its aspects and various suggestions have been put forward

for dealing with the matter. In the year 1922 a committee of the Ministry of Health began a special inquiry, its report, issued in 1924, is a very valuable piece of work. In March last we published (SUPPLEMENT, March 12th, 1927, p. 85) the report of a conference called by the British Medical Association on spa treatment for insured persons. The main discovery of this conference seems to have been that, while all sections were anxious for something to be done and genuinely willing to co-operate, there were very great difficulties in the way of doing anything. The subject was under consideration again at the congress of the Royal Sanitary Institute at Hastings in July last. Sir William Willcox there delivered a lecture on the effect of chronic rheumatism in industry, and Mr. John Hatton, director of baths at Bath, outlined a scheme proposed by the British Spas Federation for the extension of facilities for treatment. Some account of these pronouncements was given in the JOURNAL of July 23rd last (pp. 143 and 145). Last summer, too, by invitation of the German Ministry of Health, a number of British medical men and representatives of industrial organizations attended the inauguration of a German committee on industrial rheumatism in Berlin, and visited various spas and special hospitals. A full account of this expedition and of some of the institutions and health resorts visited was published in the JOURNAL of September 17th last (p. 502). Last week Mr. Henry Lesser, who was among those who had thus visited Berlin, devoted his presidential address before the National Association of Insurance Committees at Harrogate to the subject of the need for clinics for the treatment of industrial rheumatism, and made the suggestion that national health insurance organizations—whether Insurance Committees or approved societies—should, with the sanction of the Minister of Health, co-operate in helping to finance the experimental clinic in London which has been proposed by the British Committee of the International Society of Medical Hydrology, and apparently sponsored by the British Red Cross Society, which, under the chairmanship of Sir Arthur Stanley, is launching an appeal for £40,000 as a foundation fund.

Commonly quoted statistics are that nearly one sixth of industrial invalidity in this country is due to rheumatic affections, that such diseases cost the approved societies between £1,800,000 and £2,000,000 each year in sickness and disablement benefit, that the nation loses more than 3,000,000 weeks of work from this cause every year, that half of this loss is caused by chronic joint disease, and that the number of insured persons suffering in these ways approaches 400,000. These figures are sufficiently serious, and if Mr. Hatton's claim can be substantiated that 87 per cent of patients are discharged cured or relieved from the hospitals at three of the principal British spas there is a clear case for a great effort to make such treatment available for insured persons. The scheme of the British Spas Federation is to take some 30,000 insured patients each year to the British spas, to place them in hospitals, in the less expensive boarding houses, or in hostels under some supervision, and to give them an appropriate course of treatment at the bathing establishments. The approved societies appear to regard such a scheme as too expensive, and some of them propose that, since the patient cannot go to the spa, the spa treatment shall be brought to the patient, as at Berlin, Hamburg and Dresden. Any such scheme in this country must be regarded as purely experimental. Though in Germany both the staffs of the hospitals and the officials of the organizations

corresponding to our approved societies appear to consider that an appreciable measure of success has been achieved, statistics are almost wholly lacking, and there is room for a reasonable scepticism as to the permanence of relief in a large proportion of the cases referred to by Mr. Hatton. No doubt much good would be done by the establishment of a well equipped clinic in London under proper auspices and direction. Possibly approved societies might in due time recover in diminished sick pay whatever contributions they might be able to give. The main value of the clinic would, however, consist in the improved facilities and opportunities which it would afford for that clinical and pathological observation and research which is so necessary for further success in combating a baffling and obstinate national scourge.

#### THE PANEL CONFERENCE

THE Annual Conference of Representatives of Local Medical and Panel Committees was held last week in the Great Hall of the British Medical Association. A full report of the proceedings is given in this week's SUPPLEMENT. The representatives were mainly engaged upon two matters, the one of major, the other of minor, importance. The former was the consideration of what has come to be called the "disciplinary machinery" of the national health insurance medical service, the latter was the question of devoting a small portion of the National Insurance Defence Trust Fund to encouraging the candidature of suitable medical representatives for the House of Commons. Last year's Conference gave to the Insurance Acts Committee a general authority to negotiate with the Ministry of Health on certain lines with regard to the revision of the Medical Benefit Regulations and procedure relating to alleged breaches of their terms of service by practitioners. Some quite important alterations in detail have now been agreed upon between the Committee and the Ministry, and an entirely new and purely professional committee is to be set up within the Ministry for the purpose of advising the Minister in every case involving questions of professional conduct, before he promulgates his decision. Half the members of this new committee will be chosen from a panel nominated by the Insurance Acts Committee itself, the committee will have full access to all relevant material, and it is to be presumed that no Minister would be unwise enough to act contrary to its advice. These proposals were endorsed by the Conference as preferable to a routine recourse to the Law Courts, and they are to be given a trial for an experimental period of three years at least. On the other matter the Conference, by a narrow majority, refused to endorse the proposal of the National Insurance Defence Trustees to earmark a sum of £1,000 for parliamentary purposes. This decision was possibly a wise one in the interests of the Defence Fund and if, as may be presumed to be the case, the majority of subscribers, or potential subscribers, share the twofold misunderstanding which was apparent at the Conference. It appears to have been thought that such earmarking would convert a non-political into a political fund, and so entail certain consequences. There can be little doubt, however, that the fund must be regarded even now as a political one, and so subject to any legal or other provisions which apply to such funds. Political purposes are none the less political because they are not associated with any particular party. Again, it seems to have been assumed that "the support of a member of Parliament" was aimed at, whereas the most frequent use of such a fund would be to give relatively small sums to a number of candidates by way of contribution towards their election expenses. It is found that a friendly and helpful act of this kind, in cases adjudged

suitable is calculated to produce results in the direction of securing such information, sympathetic attention, and willing advocates, which are well worth the encouragement. It is to be hoped that the decision of the Conference in this matter will merely result in increased attention and support being given to the Parliamentary Elections Fund of the British Medical Association.

#### THE INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY

THE Annual Congress of the International Society of Medical Hydrology took place in Italy from October 12th to 16th under the presidency of Senator Professor Umberto Gabbi. Representatives of fourteen nations, numbering in all about 250, were present the first three days of the congress were passed in Rome. On October 12th the inaugural meeting was held by invitation of the Government in the Campidoglio (Senate House) on the Capitol the address of welcome being delivered by Signor Pietro Fedele, Minister of Public Instruction, who was supported by the Governor of Rome, the Dean of the Faculty of Medicine the Director-General of Public Health and other distinguished Romans. The afternoon was devoted to scientific business at the University of Pavia. The use of water in acute disease" being read by the President Professor Strassmann (Vienna), Dr. Fortescue Fox (Chairman London) and Sundell (London). In the evening the delegates were received at the Palazzo Chigi by Signor Mussolini who expressed his pleasure at seeing members of so many nations united on Italian soil in the common fight against disease. On the next day the members were shown the principal sights of Rome and were received at the Chamber of Deputies, where they were entertained for tea afterwards they went to the tomb of the Unknown Warrior, where the President laid a wreath. The next place visited by the congress was Montecatini a well known watering-place near Florence which has been considerably developed of late years largely owing to subsidies granted by the Italian Government for the purpose. Here they were welcomed by Senator Professor Queirolo (Pisa), the honorary director of the baths and shown the new bathing establishments which but for an unlucky accident would have been officially opened on this occasion. During the next day further papers were read by Professors Valenti (Milan), Marfisi (Naples), Razzano (Ischia) and Charvanc (Algiers) and Drs. Burt (Buxton), Judd Lewis (London), Joseph Race (Buxton), and Leirevolles (La Bourboule). In the evening a banquet was given at the principal hotel by the municipality and this was followed by a dance at the "Sporting Club." Salomaggiore, a spa lying between Parma and Milan was next visited. The establishments here are on a most lavish scale the Government having, since the war, advanced over three-quarters of a million pounds for their completion. Papers were here read by Professor Luigi Zoni (Milan) and Dr. Mongeot (Rovato) and Woodmansey (Harrogate) the subject being the action of mineral waters on ferments and micro-organisms. On the next day the congress broke up some members proceeding to Parma where they were shown round the University and new hospital by the President Professor Gabbi, who occupies there the chair of clinical medicine.

#### WHAT IS COMPARATIVE MEDICINE?

At the meeting last week of the Section of Comparative Medicine of the Royal Society of Medicine Dr. Braekel put a most pertinent question and raised matters of great fundamental importance when he asked "What is comparative medicine?" At the Edinburgh meeting of the British Medical Association the newly formed Section of Comparative Medicine debated a somewhat similar matter,

and, as we publish reports of both discussions this week, it may be opportune to examine the result. Medicine itself must be regarded as a collection of more or less unrelated sciences united by the single common factor of their bearing on health, whether of man or of his animals. In the past it has often been believed that veterinary medicine *per se* was comparative medicine, and while it is true that the collection of "medicines" studied by the veterinary surgeon must be to some extent comparative, it is equally true that comparative medicine cannot exclude man. There has also been a tendency in the past to limit comparative medicine to a consideration of veterinary diseases communicable to man, but it is now fully recognized that this view is far too narrow. Comparative medicine is most frequently conceived as the comparison between human and veterinary medicine but some of the speakers in Edinburgh pointed out that it is even greater than this and Dr. Biddell now confirms them. It is not a complete entity like human medicine or like equine or bovine or canine medicine or any of the other branches into which veterinary medicine is divided. It is really a method by which it should be possible to abstract from each of these their common fundamental truths. Comparative pathology is thus envisaged by one of the speakers at Edinburgh as the comparison of host reactions to a common stimulus; the comparative method will attempt to find, for example, an explanation of why the histology of the tubercle varies in different animals and why it resembles in the one animal, lesions caused by other chronic infections. Comparative immunology will, in a like manner, attempt to explain natural immunity, and so with the other branches. In this way will be formed a pure pathology, a pure immunology, and so on. These subjects grouped together will form pure medicine. In other words, this is the method by which pure medicine, as opposed to applied medicine will be abstracted from facts discovered in its divisions, the method by which general theories will be built up and in turn prepared for reapplication in a new and wider sense. Looked at in this light comparative medicine is almost synonymous with pure medicine and until the day when such a metaphysical concept can be called into real existence will of necessity have to replace it. Comparative medicine is, then, mainly a matter for to-morrow. Co-operation between human and veterinary medicine has been frequent in the past, it must be continuous in the future. The discoveries made by this co-operation must be first of all analysed and then synthesized into new and more comprehensive theories. It is only in this way that an all embracing view of disease and the processes of disease is possible, and it is only when this becomes a reality that a war of extermination against the causes of disease can be successfully waged.

#### THE THAYER LECTURESHIP

WILLIAM SUMNER THAYER is well known in this country, and is not without honour in his own country. He was born on June 23rd, 1864, and after graduating at Harvard went to work under Osler at the Johns Hopkins Hospital Baltimore where he has remained ever since except when during the war, he was Brigadier-General of the Medical Corps and Chief Consultant of the Medical Service of the American Expeditionary Force. He was professor of clinical medicine 1905-18, physician-in-chief 1918-21 and now is Emeritus but active as of yore as shown by his recent elaborate monograph *Studies on Bacterial (Infective) Endocarditis*, noticed in our columns last year (1926 II, 843). Like his former chief, the late Sir William Osler, he has captured not only the minds, but the hearts of his colleagues and pupils and so it is no matter for surprise that on May 18th last, at Washington,

D C, his friends presented to the Johns Hopkins Medical School the deed of gift (over 16,000 dollars) to be held in trust by the University as an endowment for "the William Sidney Thayer and Susan Read Thayer Lectureship in Clinical Medicine". This income is to provide one or more lectures annually at the Johns Hopkins Medical School by men distinguished in clinical medicine, pediatrics, neurology, or borderline branches. The graceful introductory speech of the chairman, Dr Frank Billings of Chicago, was followed by the presentation address prepared by Professor L G Rowntree, who originated the idea of thus honouring his former teacher. Provost Ames, who spoke not only as representing the Johns Hopkins University but as a grateful patient, accepted the lectureship on behalf of the president of the Board of Trustees. Other informal addresses were given by Dr Simon Flexner, J M T Finney, Thomas McCrae, T B Fitcher, L A Conner, and Charles Minor, old friends and associates. Professor Thayer replied in a speech charming in its reminiscent vein. He confessed that at the beginning of his career and for many years afterwards his desire was to be a pathologist, but the necessity to earn a living obliged him to set up a door-plate in Boston, and during its three weeks' existence he had two patients, then by accident he heard from a friend of a post-graduate of "differentiating physician" to sort out the patients—and in thirty-six hours he was in Baltimore. Looking back on the experience of these years his opinion is that above all the art of medicine demands practice, and a good diagnostician is not born, but made by experience. There are, he goes on, "few short cuts in medicine. All the acquisitions of recent years have not shortened by a day the time that he who would be a skilled clinician must pass by the bedside." This lectureship is exceptional in being established during the lifetime of a physician, but it also perpetuates the memory of his noble wife, who, when fatally ill, urged him to go on the American Red Cross Mission to Moscow in 1917, knowing full well that she would not live to welcome him back.

#### YELLOW FEVER IN WEST AFRICA

When the work of Reed and his associates, and its practical application to Cuba and Panama, were followed by Noguchi's discovery of *Leptospira icteroides*, and the preparation of a serum and vaccine, it seemed that the world was in a fair way to be rid of yellow fever, but the disease still appears from time to time on the west coast of Africa, often in isolated cases, and attention has turned again to that locality, from which, according to Carter, the American yellow fever originated. In the course of an address delivered in Holland last March, Balfour recalled the demonstration by Theiler and Schüld that the relation between Weil's disease and yellow fever was far from clear, and said that the etiological significance of the *Leptospira* was by no means certain. It has been asserted in a recent United States public health report that the causative agent of yellow fever is still unknown. Schuffner and Moeltzer have been unable to distinguish between *Leptospira icteroides* isolated from a yellow fever case at Vera Cruz and other *Leptospira* preserved by the Tropical Institute at Amsterdam, and some recent reports from West Africa emphasize these uncertainties. In eight cases (with five deaths) recorded by Aitken and Smith in Nigeria, the clinical picture differed definitely in several points from the authoritative description by Carter of classical yellow fever. In every case blood culture on Noguchi's medium was negative, injections of specific serum saved none of the four patients to whom it was given, and careful examination of the fatal cases revealed an unexpected variety in the

nature and extent of the pathological conditions present. Aitken, writing from French West Africa, records the recovery of a patient after four injections of 50 ccm of Noguchi's serum. The first three injections were followed at about a day's interval by a return of vomiting and other serious symptoms, suggesting, perhaps, that benefit was wrongly attributed to the serum, the phenomena representing really an instance of the occurrence of the repeated prostrations and remissions which Le Fanu has noted among his cases on the Gold Coast. Aitken adds that each injection was followed by a violent reaction with rigors, and he regards this as normal, but it did not occur in the cases treated by Aitken and Smith. In the annual medical report of the Gold Coast for 1925-26, Le Fanu gives an account of four successive cases treated effectively on new lines. Assuming the disease to be spinochaetal he gave novarsenobillon, he had seen many cases treated in other ways, and concludes that this arsenical preparation may be given with advantage in doses of 0.45 gram for men and 0.3 for women, at any stage unless anuria has set in. An important adjunct—the credit for the suggestion is given to Balfour—was the administration of glucose to maintain the nutrition and liver function, and thus to avoid the production of toxic fermentations. The glucose is added to bland fluids given freely in small quantities, or where nausea was present by intravenous injection of a 5 per cent solution. In Le Fanu's view these methods mark a definite advance in the therapeutics of yellow fever. The International Health Board, which played so large a part in adding America of "yellow fever," has appointed a commission to study the African problem on the spot, in co-operation with the officers of the British Colonial Service.

#### MEDICAL EDUCATION IN CHINA

Dr J L Maxwell, the secretary of the Chinese Medical Association, contributes to the July issue of the *China Medical Journal* an interesting account of the present position of the medical schools in China. He states that of these nine schools, four are still running more or less normally, two continue under a skeleton staff, and three are closed. One of these may, however, be reopened in the autumn after complete reorganization, but grave doubts are felt as to the possibility of beginning work again in the other two. Dr Maxwell fears that the interference in medical education consequent on the military disturbances in China will have very serious results. There is at present a decrease of nearly 50 per cent in the output of medical practitioners from the leading medical schools in that country, the previous supply was far below the needs even of the mission hospitals, and it will be very long before the former figures can again be reached. Moreover, many of the Government and other medical schools have been closed, and the financial condition of others is grave. The prospect of providing an adequate medical profession for the country has, therefore, receded very seriously. Dr Maxwell adds that the mission hospitals—nearly 300 in number—are largely dependent on these schools for their staffs, and in the past have been grievously hampered by the difficulty of obtaining fully qualified Chinese medical practitioners. This evil will now be intensified, and already foreign countries are carrying a heavy burden in staffing hospitals, than they can continue to bear. The death and invaliding rate among these doctors is believed to be heavier than in any other class of foreign workers. It is suggested that in all boards and committees should consider carefully the difficult situation that is now developing in mission hospitals, with a view to making more use of the valuable Institute of Hospital Technology, which has been in operation a short time if it is thought that its students might relieve hospital staffs of much burdensome incidental work.

## THE SCHOOL OF BIOCHEMISTRY, OXFORD

THE School of Biochemistry in Oxford dates from 1887, when Dr J S Haldane began to teach the subject within the department of physiology which had been established some five years earlier, when the then regius professor of medicine (Sir Henry Acland) had induced Buidon Sander on to leave University College, London. Recognition of the value and interest of the study of the chemistry of living things grew, and in 1920 University opinion was prepared gratefully to accept an offer from Mr Whitley of Trinity College, which made possible the foundation of the chair of biochemistry, Benjamin Moore was its first occupant. After his premature death he was succeeded in 1923, by the present occupant, Dr R A Peters. The need for providing additional accommodation for physiology had long been patent, and it was decided

to do this by erecting a new building for biochemistry. It is linked with the physiological laboratories by a new lecture theatre seating about two hundred which is to be used in common by both and has been so used since October, 1925 a year later the biochemistry classes were transferred to the new building and the move was practically complete. Last January, although some of the rooms are not yet quite finished the department is now working as an organic whole so that the University deemed it appropriate to celebrate this addition to its resources by a formal ceremony on October 21st, the last day of St Luke's summer with which this year has tardily been graced.

The Chancellor, Viscount Cave (Lord Chancellor of England) gave a short address in the Sheldonian Theatre to a distinguished audience which thanked him through the Vice-Chancellor, and then followed to the new laboratories which stand four square on a piece of ground, off South Park Road which was once shrubbery. The walls are of brick faced with white cement with in order to secure plenty of light lofty steel windows the whole has something of the effect of those business premises or reinforced concrete with a wide expanse of window in metal frames, a style which, when it was introduced a few years ago was much admired by many architectural amateurs.

The ground floor, in addition to the conjoint lecture room already mentioned contains several research rooms, rooms for centrifuge and photography, various offices, and rooms for assistants. The first floor, mainly devoted to teaching, contains large classrooms placed side by side with steel and glass partitions which can be shifted if it be desired to alter the arrangement of space. From this floor a passage leads to the library, which has been constructed out of the old physiology lecture room. On a mezzanine floor several rooms have been formed, including one for gas analysis, and another lined with cork for constant temperature work. The second floor is wholly for research, in addition to ordinary research rooms and one for the professor, there is an aquarium room supplied with water from a special part of the roof, which is tiled instead of being covered with asphalt. Another part of the roof is flat and upon it has been placed a small open air laboratory.

The architect, Mr H Redfern, RIBA, is to be congratulated on designs which meet very well the special conditions with which he had to deal.

In spite of the benefactions of Mr Whitley for the chair, and of the Rockefeller Foundation for the building the University is itself undertaking a serious pecuniary responsibility. It has agreed

to contribute a sum of £25,000 or its equivalent in annual income towards the general maintenance of the new department. The Rockefeller Foundation has also given £20,000 towards maintenance, for the building it gave £55,000, and the University £3,000 to meet the capital expenditure of the department of physiology.

Those responsible for the conduct of the department are, however, very desirous of obtaining further funds, chiefly for the purpose of providing studentships to enable selected men to stay in Oxford for one or two years to obtain training in research work. Other scientific departments feel the same need and it is said that until it is properly met our country will not make the best possible use of the brains of the younger generation of the University of Oxford.

SCHOOL OF BIOCHEMISTRY OXFORD

## England and Wales.

### LIVERPOOL MEDICAL SERVICE

THE Liverpool annual medical service was held at the Cathedral on Sunday, October 16th. The Bishop of Chester (Dr Luke Paget) preached an eloquent sermon dealing with the comradeship between medicine and theology in all medical work, and the necessity that their members should co-operate. He alluded to the fact that his father was a surgeon and paid a warm tribute of admiration to the late Sir Victor Horsley. The Bishop of Liverpool conducted the service and the lessons were read by two medical men. There was a large congregation, general and medical, some eighty medical women and men attended in robes. The collection which amounted to £119 5s., was in aid of the Royal Medical Benevolent Fund.

### NEW PHYSICS LABORATORY IN THE UNIVERSITY OF BRISTOL.

Sir Ernest Rutherford, O.M., president of the Royal Society and Cavendish professor of experimental physics in the University of Cambridge, opened, on October 21st, the Henry Herbert Wills Physics Laboratory, the latest addition to the buildings of the University of Bristol. This acquisition is the gift of the late Mr Henry Herbert Wills, pro-chancellor of the University, who provided £200,000 for its erection and equipment. The laboratory, which is built in the Renaissance style, is L shaped, the long arm being arranged with a view to future extensions. The carvings in the spandrels over the main doorway represent the dispersion of sunlight by a prism, and the tracks of alpha particles from radium, thus illustrating early and modern discoveries in experimental physics. On the ground floor there are research rooms,

power rooms, and workshop, on the first floor more research rooms and laboratories for senior pupils, on the second floor laboratories for senior students of optics and laboratories for junior pupils, on the third floor is the library, several classrooms and private rooms for the staff. A large lecture theatre on the first floor will accommodate an audience of 300. A smaller theatre beneath it has a minimum seating capacity for 130, the acoustic properties of both of these theatres have received special consideration. At the junction of the two arms of the building is a tower 64 feet square which contains two large rooms available for research work, its roof is flat in order to facilitate certain forms of outdoor experimental work. In equipping the new laboratory provision has been made for the researches of the existing staff and for the present requirements as regards teaching, a small reserve fund has been formed for future needs. A professorial chair in theoretical physics has been established and two new Fellowships.

#### A CONValescent HOME FOR BIRMINGHAM PATIENTS

The Minister of Health opened new buildings at a convalescent home in Tyn-y-coed, overlooking the valley of Llanrwst, on October 1st. This home has enabled many thousand Birmingham workers to recuperate after illness, and the number of applications has increased so considerably that it has been found necessary to expand the accommodation from sixty-five beds to 125. In the course of the proceedings it was stated that through the Hospital Saturday Fund, the promoter of this work, no fewer than 117,540 patients had already been treated. The cost of this extension was estimated at about £34,000, half of which has now been subscribed. Mr Neville Chamberlain commented on the gratifying fact that the new building resulted from the voluntary efforts of the working population of Birmingham. The achievement was the more meritorious because of the recent severe unemployment and underemployment in that city. He added that the work of the convalescent home was not merely curative, it was also preventive, and would result in the saving of money as well as of health.

#### HARTLEPOOL INFIRMARY NEW OPERATING THEATRE

In consequence of the steady increase in surgical work at the Hartlepool Union Infirmary a new operating theatre has been equipped at a cost of £2,350. The walls of the new theatre are coloured green in order to avoid glare, and all the fittings are fully modern. The chairman of the board of guardians, presiding over the formal opening on October 10th, explained that for many years such an improvement in the surgical department had been urgently necessary, but financial considerations had prevented anything being done. Insufficient accommodation at the voluntary hospitals had, however, rendered some action necessary, since in the event of a serious accident affecting several people that institution was obliged to provide beds. He added that the cost of upkeep is lower than that of any other similar establishment in the North of England—namely, 7s 4d a head, as compared with 9s 8½d, which was the average for Northumberland, Durham, and the North Riding of Yorkshire. Dr T. G. Ansley, senior medical officer, stated that for many years operations had been conducted in a theatre improvised out of a ward when inadequate ventilation had rendered the use of the room impossible for this purpose, and for the last four years the surgeons had been consequently compelled to operate in the wards. During recent years verandahs had been added to accommodate over fifty beds, a nurses' home had been built and electric light had been installed. It was proposed to provide before long helio-therapeutic apparatus, moreover, the nurses' home required further enlargement.

#### MALARIAL THERAPY IN LONDON MENTAL HOSPITALS

The London County Council has approved, as an experiment for one year, a scheme for the co-ordination of the work done at the mental hospitals in the county of London in connexion with the treatment of general paralysis of the insane by induced malaria. The scheme provides that all cases of general paralysis of the insane treated by malaria shall be reported to the central pathological labora-

tory. A special medical officer is to be seconded to the central laboratory whose duty it will be to maintain the records and, under the direction of the director of the laboratory, to give his time to research work on the malarial treatment of general paralysis. It would be his duty also to visit the various mental hospitals and to report abnormalities in cases under treatment. A return of all patients discharged after malarial treatment is to be made to the central laboratory, and the special officer will follow up the after-history of such cases, visiting them when desirable, and making such arrangements as are practicable for them to undergo tests at stated intervals. The expenditure is expected not to exceed £480 for the experimental period of one year.

#### ENLARGEMENT OF ERESHAM HOSPITAL

Towards the end of last year the committee of Eresham Hospital decided that this institution must be enlarged, at an estimated cost of about £18,000, and that the most urgent part of the work should be done first. An appeal was made for £9,000 for this first part, and £8,378 has been subscribed or promised, but the work now completed has actually cost £11,764. There is thus at present an outstanding debt of £3,386, and it is estimated that the second part of the enlargement scheme will involve an additional £4,500. On September 28th the portion of the extension already completed was opened. The new accommodation includes a public ward for women, with twelve beds, an improved operating theatre, anesthetic room, and dressing room, a ward for children, containing four beds, a temporary x-ray room, eight nurses' bedrooms, and an additional bathroom, enlargement of the kitchen, and various accessories. Eresham Hospital has been established for fifty-one years, and it is confidently expected that the further funds necessary will be obtained.

## Ireland.

#### MEDICAL REGISTRATION COUNCIL

The Medical Registration Council for the Irish Free State has been completed, and its constitution is as follows:

Executive Council (Irish Free State Government) Dr H. K. Moore and Dr J. N. Meenan  
University College, Cork Professor J. Dundon  
Royal College of Surgeons Sir Arthur Chance  
Royal College of Physicians Professor T. G. Moorhead  
Apothecaries' Hall Dr E. Magennis  
Trinity College, Dublin Professor A. F. Dixon  
University College, Dublin Dr D. J. Coffey  
General Medical Practitioners of the Free State Dr R. J. Rowlette and Dr Maurice Hayes  
University College, Galway Professor Stephen Shea

The members of the Council, according to the Medical Practitioners Act, will hold office for five years, and any vacancy arising from death, resignation, or disqualification will be filled by the body which the deceased or resigned member represented, the new member to hold office for the residue of the term of the deceased or resigned member. The duties of the Council will be the administration of the Act, including the preparation, establishment, and maintenance of a register of practitioners in the Free State. When the Council has fixed a date for the establishment of the register—not later than ten months after the passing of the Act—the Minister for Local Government and Public Health, by notice in *His Official Gazette*, will declare the establishment of the register is from that date.

#### DUBLIN MEMORIAL TO PROFESSOR ADRIAN STOKES

A meeting for the purpose of establishing a memorial to the late Professor Adrian Stokes, of whom an obituary notice appeared in our issue of October 1st (p. 615), was held in the School of Pathology, Trinity College, Dublin, on October 17th. The new Provost, Mr Edward J. Gwynn, presided, and those present included many leading members of the medical profession in Dublin. The Provost briefly reminded his hearers of the special connexion of Adrian Stokes with the University of Dublin, and the many reasons why his name ought to be perpetuated there, and in so doing paid a fine tribute to Dr Stokes as a sportsman. Sir John W. Moore in proposing the establishment of an

Adrian Stokes memorial, spoke of the ancestral connexion of Adrian Stokes with Trinity College and its famous school of medicine, of his brilliant professional career, and of his splendid scientific work while on active service in France. Professor T. Gillman Moorhead, in seconding the resolution, said that the phrase "well beloved" undoubtedly applied to Adrian Stokes whom above all he liked to remember as a friend. "We honour ourselves," said Professor Moorhead, "in honouring him, and we want to perpetuate his memory in this school." The resolution, the terms of which are indicated in a letter from Professor J. W. Bigger and Mr. Seton Pringle, published this week in our correspondence column, was passed unanimously, and an executive committee was appointed.

#### DENTISTS BILL, 1927 (IRISH FREE STATE)

The Minister for Industry and Commerce (Mr. McCulligan), in dealing with the second stage of the Dentists Bill, stated that its object was to regulate the internal arrangements with regard to the control of dentists in the Irish Free State, and was pretty well identical with the international agreement regarding the control of medical education. The bill, he said, was with the exception of a few minor changes, similar to the bill that was before a former Dail. To gather the full effect of the proposals attention should be paid to the Medical Practitioners Act passed last June. The bill provided that the control of dental practitioners should be in the hands of Irishmen in the Free State. Sir James Craig (Dublin University) said that he had supported a second reading on two former occasions, but in this bill he found Clause 43 objectionable. It said that "it shall not be lawful for any person on or after the date of the passing of this Act, to practise, or hold himself out, whether directly or by implication, as practising, or being prepared to practise, dentistry or dental surgery, unless such person is a registered dentist." A sub-section allowed the performance by a registered medical practitioner of any surgical operation in connexion with the tissues of the mouth or jaws, or the giving by a registered medical practitioner of any dental treatment, advice, or attendance in urgent dental cases. It was ridiculous, he said, to put the word "urgent" into the bill. He did not approve, either, of the principle that medical men should not be allowed to practise dentistry. For instance, if a poor laborer came to the dispensary doctor suffering from a severe toothache, the doctor, if he extracted the tooth, would be acting illegally under this bill. Was the man to be sent perhaps, twenty miles away to a dentist, and then have to pay a fee for that which he could have had for nothing at the dispensary? Dr. O'Dowd (Roscommon) and Dr. Hennessy (Dublin City South) also opposed the sub-sections limiting the practice of future medical practitioners.

## Scotland.

#### IMPROVEMENT OF THE PUBLIC HEALTH IN SCOTLAND

In an address delivered by Dr. William Robertson, M.O.H. Edinburgh, in the Central Hall, Edinburgh, on October 16th, he said that the city had passed through various reformations of which one of the most important had been that in public health. Koch, by his discovery in 1882 of the existence of the tubercle bacillus, and his subsequent work in growing it outside the human body, had awakened the scientific world to the importance of relieving the whole problem of possible prevention and cure. In 1900 there had been 548 deaths from pulmonary tuberculosis and 270 from non-pulmonary tuberculosis in the city of Edinburgh. A quarter of a century later, in 1926, the deaths from these two sources were respectively 356 and 126. The saving of life could not, however, be rated in actual figures. It was evident that more people were being kept alive to earn wages and to be serviceable citizens. The successors of the present generation would reap the benefits of the present-day agitation in favour of tubercle-free milk supplies for local authorities were now armed with strong powers for dealing with cows that spread infection. More-

over, slum clearance and improvement schemes were, in Edinburgh, about to transfer more than twenty-five thousand persons to better surroundings. The infantile mortality figures had already been reduced from 143 deaths per 1,000 births in 1880 to 80 per 1,000 recorded in 1926. This meant an annual saving of 63 lives among every 1,000 births. Thus money had been saved, lives had been protected, and the expectation of life had been increased in Edinburgh by 17 years.

#### A MATERNITY AND CHILD WELFARE HOSPITAL

The value of a maternity hospital in a large industrial area is emphasized by Dr. G. V. T. McMichael, medical officer of health for the burgh of Paisley, in his annual report for 1926. When the Barshaw Maternity and Child Welfare Hospital was opened in 1921 eighteen beds were provided for ante-natal cases, for abnormal and complicated labour, and for those necessitous patients whose circumstances rendered safe confinement at home impossible. During 1926 arrangements were made to utilize one of the children's wards for maternity cases, the accommodation for which is now thirty beds but the demand is increasing. Dr. McMichael believes that it will be necessary before long to devote the whole hospital to maternity work. The number of admissions to the ante-natal ward reached last year the record total of 182, as compared with eighty-three during 1922, the first year of the hospital. The success of the ante-natal clinic is attributed largely to the fact that hospital treatment for diseases of pregnancy is always available at Barshaw. The number of confinements in the year under review was 388, as compared with 201 in 1922. Patients treated in the maternity wards are required to contribute according to their household income. When the hospital was opened two wards were allocated to children, one for medical cases and one for minor surgical cases but owing to the increased demand for accommodation for maternity patients only one ward is now available, and arrangements have been made for the medical cases to be admitted to the fever hospital.

#### ROYAL PHYSICAL SOCIETY OF EDINBURGH

At a meeting of the Royal Physical Society of Edinburgh, on October 17th, Dr. John Stephenson read a paper on "Eastern adepts and Western science" in which he discussed the reputed power of the yogis to modify the beating of the heart at will. A yogi of Bombay is reported to have been able to stop his pulse in either arm for two or three minutes, and that of the temporal artery for several seconds. Mechanical records had shown that the heart beat was slowed and made less forcible, but not completely stopped. This yogi had apparently acquired a certain amount of voluntary control over the sympathetic nervous system, but more observations were required before either the facts or the explanation could be accepted. At the same meeting a study on "The pigmentation of the rabbit" was communicated by Dr. F. A. E. Crew, who said that adult Himalayan rabbits, which normally are white with black tips on the nose, ears, legs, and tail, can be made to grow black by lowering the temperature of the environment, and white tips can be produced in place of black by raising the temperature. Local application of low temperature at any part was also found to stimulate the growth of pigmented hair. The pigmented granules had been found to originate in the epithelial cells of the hair follicles and later to pass to the growing hair. The production of pigment by low temperature was explained by the stimulation of secretion of oxidase and the consequent production of pigment by its combination with a colourless chromogen.

#### GRASS DISEASE AMONG HORSES

The serious mortality among horses in Scotland caused by "grass disease" is of great importance to farmers, and it is also of considerable interest to medical men on account of an alleged connexion with encephalitis lethargica. The subject of grass disease was discussed at a meeting of the Scottish Branch of the National Veterinary Medical Association at Gleneagles Hotel on October 15th. Professor

W. A. Pool, Director of the Animal Diseases Research Institute, Lelerton, gave an account of the history of grass disease which suggested that it was first encountered in 1907 at Bury Camp, Forfarshire. It was supposed to have spread gradually until now cases had occurred in every county in the north-east of Scotland. The disease had been attributed to various organisms, including types of streptococci in the nervous system of animals suffering from the disease, but the latest evidence suggested that these were of only secondary importance. Considerable attention had been given to the possibility of fungi causing diseases of this type. It had also been suggested that the disease was the same as botulism, but the symptoms of the two diseases were different, although four types of the *Bacillus botulinus* were recognized. The lecturer thought that the cause of grass disease was at present an open question. Professor Russell Grieg of the Royal (Dick) Veterinary College, Edinburgh, described the clinical symptoms of acute grass disease, which gave some indication as to the nature of the toxin producing them, it belonged apparently to the so-called sympathico-mimetic group. The discussion was continued by Professor Clark of Edinburgh University, who declared there was a fairly strong probability that the disease was caused by a toxin of some kind. Dr. Diverie, lecturer on biophysics in Edinburgh University, suggested the possibility of dietetic irritation of the mucous membrane as a cause. Mr. John Brown, F.R.C.V.S., who was inclined to attribute the disease to inhalation, and who said that cases occurred on uncultivated land as well as in highly cultivated areas, was among numerous other speakers.

## Correspondence.

### DUBLIN MEMORIAL TO ADRIAN STOKES

SIR,—At a meeting held in Trinity College, Dublin, on October 17th, with the Provost in the chair, it was decided to inaugurate a memorial to the late Professor Adrian Stokes, who died of yellow fever contracted during research work on that disease in Lagos.

It was the opinion of the meeting that Stokes's connexion with Dublin and with Trinity College—as student, as assistant to the professor of pathology, and as professor of bacteriology—could best be commemorated by the foundation of a scholarship, prize, or medal in connexion with the study of pathology and bacteriology in Dublin University. An executive committee was appointed and was empowered to collect funds and to consider a suitable form of memorial, the exact form of which will depend on the amount collected.

Those who would like to take part in the establishment of such a memorial to one of Trinity's ablest and most loved sons are invited to send their subscriptions to the honorary treasurers of the fund, Mr. Robert Russell, S.F.T.C.D., and Professor A. F. Dixon, Sc.D.—We are, etc.,

SETON PRINGLE, F.R.C.S.I.,

JOSEPH W. BIGGER, M.D.,

Memorial Fund

### MINERS' NYSTAGMUS

SIR,—Your issue of October 1st (p. 612) contains a very interesting letter from my friend Mr. A. S. Percival. Everyone who knows Mr. Percival entertains for him the most cordial respect, and anything that he may say deserves careful consideration. At the same time, as regards the origin of miners' nystagmus, I have difficulty in accepting his view of it. The fact remains that a good number of pits are quite free from miners' nystagmus. There are a considerable number of such pits in the area in which I work, and it is interesting to observe that no fewer than six of these are oil safety lamp pits, no other light being used. That is one group—pits from which I get no cases whatsoever. In a second group cases do occur, but sporadically, now and again I see patients from them, but not regularly. In a third group the disease seems to

be rampant, and it is to be remarked that a fair number of the pits in this last group are lit entirely by electricity. Now if I am not doing my learned friend an injustice his theory would imply that in some pits there are no men with an hereditary predisposition in other pits there are a few, and in the third group there are a great number. Dr. Hildane's theory would involve that in the first group of pits the lights are invariably excellent and satisfactory—it is to be noted that six of these pits are oil safety lamp pits—that in the second group the lights are sometimes good and sometimes bad, and in the third group they are invariably bad. Dr. Hildane may be able to assent to such a proposition, personally I am quite unable to do so.

It is to be remarked that in the reports which were published, and which I have somewhat stringently criticized in the *Proceedings* of the Institution of Mining Engineers, there is no record made of any investigation as to eye incidence. Had such investigation been made by men competent to handle vital statistics it would have been found that in many instances the disease seems to be an epidemic. That, at any rate, is how it appears to me. Just now the disease is very prevalent in one group of pits in the south-west of Scotland. In another group of pits near the centre of Scotland the disease was very rampant in one particular pit some months ago. Scarcely a week passed but what some cases occurred. For the last few months I personally have not seen a single case from that pit although there has been no change in the illumination, but the disease is now rampant in another pit not very far from the first. Then, again, we have records of cases appearing in men who have never been down a pit at all. Personally I have never seen any such cases, but the reports which have been issued of persons so afflicted leave little doubt in my mind that men who have never been down a pit still may take miners' nystagmus. The whole subject requires investigation, and that on a far broader basis than the last. I have little confidence in a committee which did not investigate the eye incidence, and which did not, with the exception of one member, pay any attention to the disorders of the eye. I incline towards the opinion that the facts which I have observed are best explained by supposing the presence of a toxin or of micro-organic life. To my way of thinking they are not explicable on the theory of defective illumination—I am, etc.,

Glasgow, Oct 15th

IRFELAND FRIGES

### ACTINOTHERAPY IN JOINT TUBERCULOSIS IN CHILDHOOD

SIR,—As I have used actinotherapy since 1914 in the treatment of osseous and arthritic tuberculosis I venture to give my views on its value. Like Dr. Huxley Martin I think the opinions expressed by Drs. Crosbie and Adam are too sweeping and pessimistic, at the same time they contain a large element of truth.

It is hardly necessary to emphasize the difficulty of assessing the value of any one form of treatment, but it may be well to point out that whenever a new therapeutic method is introduced one is immediately assailed with statistics apparently proving the almost universal efficacy of the remedy. It is only after long years of patient sifting of evidence that its degree and sphere of usefulness are established. For the last thirteen years I have treated children with bone tuberculosis by ultra-violet irradiations obtained from various sources—for example, the Hanau and Jesionek mercury vapour lamps, the long and short flame carbon and tungsten arcs. An erythema dose was used in the majority of cases. The children were treated by ordinary "conservative methods" at the same time, and all but a very small number have been kept under continuous observation to this date. Recently the records of the last 120 such cases treated with ultra-violet light up to twelve months ago have been carefully reviewed, and bear out the conclusions reached from one's previous experience, both among in-patients and out-patients. Of the 120 cases six definitely became worse, and is these improved soon after the radiations were discontinued it is possible

that the remedy produced the ill effects, thirty eight showed marked improvement which could only be attributed to ultra violet light therapy, after all other possible factors had been considered. The disease was arrested in the majority of the remaining patients but the result would probably have been as successful with ordinary conservative treatment without actinotherapy.

A study of the above and my previous cases has led me to form the following opinions:

#### (A) In the Cases Improved by Radiations

1 Some chronic cases with multiple sinu es which were not getting better or were actually becoming electric improved especially with mercury vapour lamp. It was impossible to decide before and whether patients would and which would not respond to ultra violet light treatment.

2 Cases of some months' duration with single sinu es and localized disease reacted in a similar way to the chronic cases.

3 In about a fourth of the patients the beneficial effect of "light" was shown by an increase in the calcification of the bones. The carbon and mercury vapour lamps were equally efficacious in producing this result.

#### (B) In the Cases not Showing Improvement

1 The progress of the disease in early acute cases was not arrested by light, nor was bone destruction prevented in such cases.

2 The reason for the failure of this treatment in the other cases which did not improve could not be determined. It was not due to the type of lamp used nor to the exposure, nor to the period of treatment, as these factors were all varied in different instances without result.

3 Case of pigmentation did not mean that a patient would do well—I am, etc.,

#### "THE HISTORICAL ASPECTS OF QUACKERY"

Sir—I suggest that Professor Clark's argument by which he attempts to vindicate his statement about the followers of Abrams is insupportable, because on his own confession it is based entirely on the assumption that the "electronic" methods committed them etc. to Abrams's electronic theory—a theory, which, it is conceded, posulates that the apparatus employed is of universal application in disease (destruction of tissue excepted). This assumption is incorrect. On page 19 of Abrams's *Methods of Diagnosis and Treatment*, edited by Sir James Barr, the following statement occurs: "We do not at this stage of our knowledge advance it as our own." The word "we" refers to the majority of doctors who use Abrams's methods in England, the book being fairly representative of their opinion. The word "it" refers to Abrams's electronic theory. There can therefore be no doubt of the incorrectness of Professor Clark's primary assumption. On page 33 it is stated: "reactions cannot be relied upon to furnish us with diagnoses in clinical terms" and at the top of page 24 "the unreliability of Abrams's diagnoses when it is divorced from ordinary diagnostic methods—e.g. indeed, when it is used purely as a guide to the use of Abrams's treatment methods—is discussed." This disposal of Professor Clark's questions about diagnosing cancer, etc., at all events in relation to the majority of those who use "electronic" instruments. Sir James Barr will, no doubt, deal with the question as it specifically concerns his private views. Furthermore reference to page 18 will show that the Abrams system is regarded only as an adjunct to orthodox medicine (which therefore is not for given) while reference to pages 14 and 47 is sufficient to indicate that it is not sought as a universal cure.

Widely divergent individual theories, like that of Sir James Barr and my own obviously cannot constitute the basis of agreement between British doctors who use Abrams's methods. Professor Clark wants to know what the "orthodox electronic faith" is and he shall be answered. It is solely the belief that certain phenomena, demanding in

investigation, exist. There may even be no essential relation between these phenomena and Abrams's machines.

As regards my own independent theory, I once thought that the phenomena must be mechanically explained and that Abrams's idea was probably right. Now I have arrived at the conclusion that they are psychically determined and can be similarly connected with most, if not all, medical methods, orthodox or unorthodox. I hold that their recognition will be helpful to scientific medicine and will deal quicker and more effectively with it than it has yet received my reason for thinking so being that they throw light upon the results constantly attending the use of quack and other methods, the successful operation of which from the physical standpoint appears unintelligible or improbable. I am prepared not only to demonstrate them, but to set forth the steps of inductive reasoning by which I arrive at my particular explanation of them.

It matters little what opprobrious term Professor Clark chooses to apply to qualified dissenters from inductive science, and I consider that his reply to me was an evasion of the central point. This is that he ought not to apply any opprobrious term to any of his qualified brethren, (a) because he does not make thorough investigation before passing judgement on them, (b) because even if he did, he is no more qualified than they are to determine what is or what is not sound reasoning in medical matters.

The book to which I have referred is at present the only authoritative British work on the subject of Abrams and in it not a single sentence is to be found which justifies Professor Clark's position.

I submit Sir that conclusive proof has now been afforded of the inaccuracy of Professor Clark's derogatory statement about the followers of Abrams in this country, and I am therefore going to ask him definitely to withdraw it together with his suggestion that these doctors are quacks or in any way akin to quacks—I am, etc.,

London W1 Oct 21st

J KENFICK PEID

Sir,—Professor Clark tells us that he said very little against Abrams, but he should know that it is not what he said but the way he said it that matters. He thought that a few lines of ridicule from a professor of pharmacology would be sufficient to demolish Abrams's followers. That same was tried in America but when the American Medical Association failed Professor Clark is not likely to succeed. I am going to show him that it is a dangerous game to call better men than himself quacks. No amount of evasion will now shield him. I account Gladstone did a good service to society when he showed that even the dead cannot be libelled with impunity.

He Professor Clark showed his incapacity by making charges of quackery in unsupported evidence, it was therefore unnecessary for me to adduce proof of a self-evident fact. He is now apparently content to remain in "everlasting ignorance" rather than take the advice of Herbert Spencer.

He draws some inferences which he thinks will suit his case from my address and demonstration at the South-West of London Post-Graduate Medical Association, in October 1924. It would be more to the point if he gave some quotations such as the following:

I do not ask you to-night to accept anything which I tell you until you have proved its accuracy. The only knowledge worth a trader's curse is that which a man acquires for himself and makes his own.

There is nothing in Abrams's methods beyond the competency of the general practitioner, but I wish to warn you that Abrams's methods are not substitutive of but supplementary to ordinary medical knowledge and the better you know your physiology, the more successful you will be in the acquisition of this new knowledge.

I do not wish you to infer that I consider Abrams's methods as the *summa summarum*. They are merely steps in the path of progress. The more scientific medicine becomes the simpler it will become.

There is not one word in my address which I would now alter, modify, or withdraw.

Although Professor Clark cannot make a diagnosis from a specimen of blood or handwriting that is no reason why others should be equally incompetent. The procedure, like all mine, is quite simple, but certain precautions have to be taken, an important one is that there should be no

contamination by untutored fingers. As Mr Legge would say, you should cultivate the thinking hand. I succeeded the first time I tried. I would advise Professor Clark not to get despondent over his ineptitude, take the advice of Herbert Spencer, and follow the example of Bruce and the spider—try, try, try again. I have myself heard men denounce Pasteur and Lister who were afterwards sorry for their temerity.

I was under the impression that I have often said that there should be no one method in medicine. The oscilloclast is not always available, nor is it always necessary. You can then fall back on the expectant method, which has been long and widely practised in orthodox medicine. This is less cumbersome than the oscilloclast, and has the great advantage over pharmacology that there is no risk of poisoning your patient, who is just allowed to live, or die a natural death—fortunately the vast majority live, hence expectant treatment is a profitable business.

Professor Clark says "Sir James Barr is the most distinguished electionist in this country." This may or may not be intended as a compliment, probably not, but as one who has always weighed against mere authority, and held that no enlightened individual should accept any doctrine which did not accord with his own reason, I can treat the compliment with the contempt which it merits. There are in this country many who have had much more experience with Abrams's methods, and there are hundreds here and abroad who have accomplished feats which I never attempted.

He is very cynical about Abrams's methods of treating tuberculosis, which seem to be beneath his contempt. Well, they are the best that I know of. Some time ago I said that Sprahlinger's treatment may be better, but I did not know Sprahlinger's, and until its superiority was established I would continue to recommend Abrams's.

Six weeks ago I saw, with an Abrams practitioner, a gentleman suffering from pulmonary tuberculosis, who had been recommended by his orthodox medical advisers to go to Diox. I agreed with my friend that he should have a course of Abrams's treatment, including the gamboge print and the yellow silk blouse. I saw him again a few days ago and he was cured. He had gained flesh and colour, his cough and expectoration had disappeared, his temperature was normal, his vital capacity had greatly improved, he could count over forty in one breath, which is his previous limit was under twenty. He said that he felt perfectly well and could walk any distance, but he had no intention of swimming the Channel. He returned home this week-end.

When Professor Clark can do better than that I shall adopt his methods, but I am afraid that I shall be a very long time dead before that happens.

In Abrams's methods the senses of hearing and touch are diligently cultivated, while the most easily deceived of all our senses, sight, takes a subsidiary place, though it is never neglected. I am afraid that life is too short to teach Professor Clark the effects of colour vibrations, though they only occupy an octave of light.—I am, etc.

London Oct 22nd

JAMES BARR

SIR,—There is no need for Professor Clark to point out to homoeopaths the manifest absurdity of believing that the thirtieth dilution of a drug contains a single molecule, atom, or election of the drug. The homoeopath knows perfectly well that his high dilutions do not contain any matter at all—that is, in any of the forms under which matter is recognized by modern physics. But surely Professor Clark is not so wedded to matter that he has forgotten the existence of that which is equally demonstrable, though immaterial—that is, energy.

Professor Clark considers it absurd to believe that these dilutions have any effect whatever. It is, of course, absurd and inconceivable, but then inductive science is not concerned with inconceivabilities, it is based on experiment under proper controls. The argument from inconceivability is not an argument which any real scientist will allow to be raised. If Professor Clark will refer to the Horder Report on the Chronometer of Boyd to the Royal Society of Medicine he will find that, however inconceivable it may seem,

drugs in high dilutions do produce effects which can be demonstrated.

Professor Clark suggests that homoeopaths are opposed to orthodox medicine. This is a misconception. Homoeopaths are not opposed to orthodox medicine but are opposed to orthodox medicine-going, which is a very different thing.

As to homoeopathy being "opposed to the chief basic theories of chemistry and physics," I have heard Sir Oliver Lodge, whose knowledge of physics and whose good faith will not be questioned, state publicly that in his opinion homoeopathy, by reason of their concepts, was the most likely to understand and apply the findings of modern physics.

In conclusion—homoeopathy is not a "fath," or a "cult." It rests on the tripod of observation, experiment, and induction, and can thus justly claim to be scientific—I am, etc.

Liverpool, Oct 22nd

F B JENIN

#### A PROPOSED ASTHMA RESEARCH COUNCIL

SIR,—In the article on page 746 of the JOURNAL for October 22nd you quote the assertion in the notice of the formation of this council that, though palliatives have been found, "no certain cure exists," and, further, that "the cause of asthma is unknown." There is, of course, a great deal of truth in this assertion, but it does not contain the whole of the truth, and suggests an attitude of hopelessness which is very discouraging to the unfortunate asthmatic. There is, truth, no certain cure for every case, but it is certain that many cases are cured. Those who care to study the illuminating experimental researches of Dixon, Bradie, and Ransom will obtain from them much information as to the cause of asthma. They will learn that an exciting cause for the attack may be localized in the nose, and should then be sought for and removed. Even though the predisposing cause may not necessarily be done away with, a vicious circle may be broken and a practical cure brought about. There are many cases in which the removal of an ill-disposed has resulted in the complete disappearance of the asthmatic attacks. It is extraordinary, however, how long patients with asthma are allowed to go on without rhinological treatment, even in the presence of very obvious nasal disease, and thus "distressing and incapacitating" disorder unnecessarily prolonged.—I am, etc.

JAMES DIXON (JUNR)

#### DRIED COMPLEMENT IN THE TROPICS

SIR,—In two recent letters in the JOURNAL Dr. Neave Kingsbury (September 17th, p. 518) and Major Anderson, I.M.S. (October 8th, p. 665), relate their experience of the use of dried complement in the Federated Malay States and India respectively. Both agree either that (a) the sample used was not a representative one or (b) that dried complement is not suitable for the tropics. The age of the dried complement at the time of trial is not stated in either letter, and judging from a short experience of dried complement in England (some ten or twelve tests) I am convinced that this is the vital point. The complement I used was also a (crude) preparation, and the claim as claimed by the makers I found to be true, with one exception—namely, that the titre would keep practically indefinitely. Using a supply from three to (?) six months old, which was stored in an ice box, I had very satisfactory results. Titres varying from 1 in 40 to 1 in 65 or 1 in 100 were obtained. The Wassermann method used was as follows: Medical Research Council elaborated by Colonel Harrison.

On the other hand, dried complement from the makers twelve months old was found to be inert. I found no difficulty in getting a clear solution, and the method adopted was to shake out the granular material evenly on to the surface of normal saline (not distilled water directed) in a watch glass. After a little time a portion not dissolved was broken up with a glass rod.

I am fairly confident that dried complement, such as I

used would be valuable in the tropics, provided small fresh supplies could be obtained direct from the makers—I am, etc.,

Bath Oct 8th J COVIL, M.B., Lieut Colonel (Ret.)

SIR—In connexion with the reference to dried complement in the tropics (Dr Nerve Kingsbury, September 17th, p 518 and Major Anderson, October 8th, n 663), we were asked some years ago if dried complement could be made and sent to the tropics in a satisfactory condition. After a considerable amount of investigation the staff of the Wellcome Physiological Research Laboratories succeeded in making a reasonably stable dry powder. Experimental batches were sent to the tropics, and after they had proved to be satisfactory we supplied the product for some time, but the demand was not encouraging and its issue was discontinued.

Our experience indicates that the dried material can probably be prepared suitable for use in the tropics, but we are informed by the staff of the laboratories that its preparation entails vigilant control and continual supervision and the loss in the process is considerable.—We are, etc.,

London EC1 Oct 18th BUTROUGHS WELLCOME AND CO

### REFRACTION "HOSPITAL"

SIR,—In your issue of October 22nd (p 753) there is a note that the opticians of Glasgow propose to establish in their city a "Refraction Hospital" for which 'the expenses of the first year would not exceed £250,' and on the lines of the 'London Refraction Hospital.' This so-called hospital is no more than a meeting place where opticians collect some few patients, examine their eyes according to their expertise, and instruct their neophytes in their methods. The inwardness of this device of the opticians would seem to be an attempt to combat the finding of the report of the Departmental Committee on the causes and prevention of blindness. "There is only one place where ophthalmology can be learnt, that is at a hospital," and so apparently the opticians devise a 'hospital' so that they may claim to be 'hospital' trained! The device is on a par with their profuse use of high sounding titles of "optologist" "ophthalmologist," "qualified ophthalmic optician," and of strings of letters which they bestow on one another. Since Scots have some reputation for a choice use of words one might have hoped that the opticians of Glasgow would have refrained from this flagrant misuse of the word "hospital."—I am, etc.,

London W1 Oct 22nd

A BISHOP HURMAN

### INFECTIVITY OF JUVENILE WARTS

SIR,—A few years ago I had under treatment a woman who had a wart on the right index finger and another on the thumb of the same hand the two warts opposing one another as if from contact inoculation. The appearance of these warts did not suggest verrucose tuberculosis. The patient, who had been a "land girl" in Cheshire during the war and for some time after said that she had acquired these warts from her work as a milker, occasionally a cow had a warty teat, and during the milking "if you make it bleed that's where you catch it yourself"—that is on the hands or finger.

Dr Piossey White believes that this transmission of warts from cattle to mankind has never been recorded previously in this country although there are numerous references to it in Continental medical writings. In the second edition of his monograph on *Occupational Affections of the Skin* (second edition 1920 p 201) he refers to a paper by Andry and Suffrin in the *Annales de Dermatologie et de Syphilis* (1908, p 545) in which it is stated that the common warts of oxen and of dogs are communicable to man. He also refers to a paper by F. Schultz on the experimental transmission of warts from cats to the human subject, in the *Deutsche medizinische Wochenschrift* for 1908.

I am told by a farmer that warts are rather common on cows' teats, even on heifers which have never calved. It

would appear that the cow is not simply infected from warts on the hands of a milker and transmits the infection subsequently to another milker. The cow seems to have a definite predilection for infective warts, and may possibly be the first stage in the cycle of infection otherwise they would not be met with on heifers before handling by the milker.

My patient's observation that the warts became infective if they were made to bleed is fully borne out by the case of ordinary juvenile warts on the human subject. In Manchester, for instance, children have a folk lore belief that they can get rid of warts if they can "sell them for a halfpenny." Thus, apparently, they have no difficulty in doing as some small boys seem quite proud to have a wart or two about their fingers somewhere it confers quite a distinction upon them. The infection, sold to the recipient, is transferred by rubbing against the wart after making it bleed.

This raises the question as to whether warts can be transferred to children and others through drinking raw (unboiled) milk. Certainly milk is predominantly a food of children, and warts are typically an affection of childhood. Blood cells can be found with fair frequency in samples of milk, and the cows which supply the milk for human consumption may have on their udders infective warts, capable of transmitting the infection to human beings if the warts are made to bleed. A prima facie case for suspicion seems to exist, though it is perhaps unsafe to put it more strongly at present.—I am, etc.,

Manchester

W J RUTHERFORD, M.D. (Lanc)

### BIRTH CONTROL INVESTIGATION COMMITTEE

SIR—There is no reasonable doubt that birth control is practised by a large number of married people of all classes. It is to be supposed that the usage may have important effects on the physical, psychological, and ethical well being, not only of the individuals who employ it, but also indirectly on the well being of the children of those persons, and therefore of the whole community. It is also probable that if birth control is desirable some methods are to be preferred to others yet up to the present little scientific study has been made, either of the comparative advantages of different methods or of the possible far reaching effects of the practice as a whole.

The subject of birth control has hitherto not formed part of medical education, and generally speaking any professional knowledge that medical practitioners may have of this question has been acquired in response to a demand from their individual private patients. In hospitals and medical schools general instruction in this subject is not as a rule given to the students, nor information to patients. Yet it is well known that in certain cases of ill health further pregnancies are clearly contraindicated on medical grounds alone.

A committee composed of scientific workers and members of the medical profession, assisted by lay workers and others interested in the problem, has been formed to promote the scientific investigation of birth control. The members of the committee differ widely in their opinions as to the desirability of birth control, but are united in the realization that the practice is widespread, and that the scientific problems which it raises can no longer be ignored.

It is realized that the results of the investigation may show that no entirely satisfactory method has at present been discovered, and work is being done to find new methods. It is hoped also that relations may be established with clinics and other organizations connected with birth control abroad, so that their experience and knowledge may be used.

The committee serves no propagandist function but desires only to establish facts and to publish these facts as a basis on which a sound public and scientific opinion can be built. The present division of medical and scientific opinion and the lack of any orthodox medical teaching on the subject are largely explained by the absence of available data on which a sound opinion can be formed.

The committee will be grateful if any of your readers who may be interested in the subject, or who possess data

that would yield information, would communicate with the honorary secretary of the committee, the Hon Miss Majoie Frier, 41B, Clarendon Gardens, London, W 2

A questionnaire has been prepared by the committee which, if filled in in sufficient numbers and in a sufficient variety of cases, will provide that quantity of accurate statistical information which is now lacking. As many of these questionnaires as may be required will be sent to any private doctor, hospital, welfare centre, or infirmary on application to the honorary secretary of the committee—I am, etc,

October 25th

HUMPHRY ROLLESTON,  
Chairman

\* \* The other members of the committee are E D Adam, M D, F R S, C P Bleker, M B, C J Bond, C M G, F R C S, Professor A M Cru-Saunders, Frank Cook, F R C S, Mrs Gladys Cox, M B, B S, Professor Winifred Cullis, D Sc, Professor Arthur Ellis, M D, Professor Julian Hurley, and Professor F H A Marshall, D Sc, F R S

### CONVULSIONS DURING GENERAL ANAESTHESIA

Sir,—Since I wrote on this subject in the JOURNAL of May 28th (p 956) you have published letters containing statements with which I disagree

The convulsions could not be confused with ether clonus by anyone who has witnessed both, and it is a pity that one or two of your correspondents should, by doing so, obscure the issue. They are probably quite easily distinguishable also from those due to atropine, which, however, I have never seen as far as I know. I do not believe they are due to impurities, because I have seen them begin, and herald of a fatality where only ether, fresh from a bottle, and of a very good brand (B D H), was used.

Neither are they due to the bomb, because many have occurred where this method was not employed (and four of those which I reported). I may add that three of the five deaths that I wrote of occurred under other methods. As I invented the bomb I should like to contradict the suggestion that it is liable to cause chest complications. Possibly, by making ether easy, administrators have been tempted to use that drug more often, and in fuller measure than they would otherwise have considered judicious. I have used it continually during these ten years, and I find that it is not so.

My experience of this phenomenon makes me adhere to my original suggestion as to its cause, and the administration of CO<sub>2</sub>, I believe, would make matters worse—I am, etc,

Manchester, Oct 8th

K B PINSON

### CONVULSIONS DURING LOCAL ANAESTHESIA

Sir,—About six months ago I administered a local anesthetic—cocaine—to a woman, aged 45, for the removal of a large lipoma from her right side. After about five minutes she had a most violent epileptiform attack. Her face became purple, and it gave us all we could do to hold her on the table. As I thought that she might have some intolerance to cocaine I at once made my incision and quickly removed the growth. She came to just as I had finished, got off the table, and walked to her room. She had never had a fit of any kind before, nor has she had one since, but she remembers everything about the seizure. I have given this same local anesthetic in hundreds of cases, but never had an experience like this. What is the explanation?—I am, etc,

Bourton on the Water, Glos, Oct 19th

PROSPER LISTON

### SECOND ATTACK OF PITIRIASIS ROSEA

Sir,—I am obliged to Dr E Graham Little for pointing out a mistake of mine in my memorandum on a second attack of pityriasis rosea (September 24th, p 549). The date of his own case was, of course, 1914, and not 1915, as I have it.

Dr Graham Little says that he thinks "the implication of infection conveyed by Dr Edleston's experience equally

uncommon", and he is surely right. This was a point which intrigued me very much, and it would be interesting and instructive to know if any similar cases have ever occurred, in which the disease seemed to be so conveyed from one to another—I am, etc,

Manchester, Oct 10th

B GORDON LEDSTON

Sir,—May I add my experience to that which has been described by Dr Gordon Edleston (September 24th, p 549). When I was a student at St Thomas's Hospital (about 1905) I found one day an eruption on my chest and arms, and went to the skin department and showed myself to Dr Strimer. By a herald spot on my arm and the character of the lesion he diagnosed pityriasis rosea. On my asking about treatment and prognosis, Dr Strimer told me that I should never have a second attack. About one year later I found myself to my great surprise exhibiting an eruption exactly similar to the previous one. I showed it to Dr Strimer, who was greatly interested, and diagnosed it as pityriasis rosea occurring a second time—I am, etc,

Ride, I W, Oct 13th

SPENCER CHURCHILL

### - A PAROXYSM OF AURICULAR FIBRILLATION

Sir,—In the memorandum by Dr Brewis on "A paroxysm of auricular fibrillation" (October 1st, p 565) he makes the statement "the auricular systole was distinctly heard". Dr Brewis is not alone in repeating such a statement, but if such a fact be not within the region of even possibility it is time that those responsible for teaching that it is should either give reason for the faith that is in them or recant. A statement of this sort detracts seriously from the value of the other statements in the memorandum.

Until we are satisfied as to the cause of the normal heart sounds it is absurd to speculate as to the cause of the abnormal heart sounds. As I have pointed out on several occasions the vibrations of the aortic valve when fibrillating are so few per second as to be incapable of producing a sound audible by the human ear. I am convinced that the sounds of the heart are produced by the movements of the pericardial fluid, and any variation of those sounds are associated with variations in the quantity and quality of that fluid together with a diminution of the negative pressure within the pericardial cavity—I am, etc,

Swansea Oct 1st

G ARBOUR STEPHENS

### PIREXIA DURING THE PUERPERIUM

Sir,—I should like to add my protest to that of your other correspondents against this new order—that we shall notify as puerperal fever any case of a lying-in woman who has a temperature of 100.4° for more than twenty-four hours. This is a form of legislation which can only bring derision on the medical profession, it is a waste of public money and a very unjust and ridiculous order. Mr Chamberlain should be made to justify this new brain-regulation. The Registrar-General's statistics will be more than funny if every woman with a headache and temperature due to mammary irritation or constipation is notified as suffering from puerperal fever—I am, etc,

#### NO 14 STATIONARY HOSPITAL

The eighth annual dinner of the medical officers of No 14 Stationary Hospital will be held on Friday, December 9th at the Trocadero Restaurant, at 7.15 for 7.45 p.m.

#### DEATHS IN THE SERVICES

LIEUT COLONEL LEWIS CASPER, Bengal Medical Service, died in a nursing home at St Heliers, Jersey, on October 27th, aged 85. He was born on June 18th, 1842, the son of Mr D. A. J.

Cameron of the Excise department Knocknido Elm and educated at Edinburgh where he graduated as M.D. in 1863 also taking the L.R.C.S. Ed. in the same year. He entered the I.M.S. as a student surgeon on March 31st 1866 passing first into Netley became surgeon major on March 31st 1870 and retired on August 9th 1891. His whole service was passed in civil employment in the province of Bengal where he was civil surgeon successively of Bickerganj, Champaran Rayshahi and Midnapur. He leaves a widow.

## Medico-Legal

### AN OSTEOPATH'S CLAIM FOR FEES

In the *BREIT* MEDICAL JOURNAL of March 5th (p. 448) a short report was given of the action brought by Mr. E. L. Macnaghten of Weymouth Street London in the Bloomsbury County Court claiming £50 for osteopathic treatment rendered by him to the wife of the defendant Mr. C. H. Douglas. The defendant pleaded that the plaintiff's diagnosis of the case was entirely wrong that the treatment given was unnecessary and unsuitable and no relief upon the provisions of Section 32 of the Medical Act 1858.

No person shall be entitled to recover any charge in any court of law for any medical or surgical advice attendance or for the performance of any operation or for any medicine which he shall have both prescribed and applied unless he shall prove upon the trial that he is registered under this Act.

Deputy Judge Stoker held that as the plaintiff was not a registered medical practitioner he could not recover fees for advice and treatment and entered judgement for the defendant with costs. The plaintiff appealed to the King's Bench Division and the hearing was reported in the *JOURNAL* of May 21st (p. 940). Their lordships Acton and Talbot J.J. ordered a new trial on the ground that they were bound by the decision of Horridge and Shearman J.J. in the case of Hall v. Trotter that an osteopath was entitled to recover fees for treatment rendered.

The action was tried anew in the Bloomsbury County Court by Judge Hill Kell on October 19th. The plaintiff was represented by Mr. A. C. Jackson and the defendant by Mr. Malcolm Hilbery and Mr. Laporte Payne instructed by Messrs. Blewitt and Son.

The plaintiff described his treatment of Mrs. Douglas and the findings upon which this treatment was based. It appeared that he had found evidence of suppurative in the antrum approximation of the first and second cervical vertebrae displacement of the coccyx and half an inch of shortening of one leg. His treatment included movement of the cervical vertebrae reduction per rectum of the displaced coccyx and administration of ultra violet rays. In cross-examination he was understood to say that he did not know the dosage of ultra violet rays and agreed that osteopathic treatment was worthless if the suffering could not be relieved by moving bones.

Sir Herbert Waterhouse consulting surgeon to Charing Cross Hospital who gave evidence in behalf of the defendant said that the movement of bones in this case could have had no effect whatever on the antrum. He had examined Mrs. Douglas and found each antrum positive normal by transillumination and there was no evidence of previous antral disease. It was quite impossible to move a dorsal or lumbar vertebra and very dangerous to attempt to move a cervical vertebra. Clinical and x-ray examination showed the spine to be normal. The coccyx could not have been moved by the plaintiff without an anaesthetic on account of the intense pain that would have been caused. There was no evidence of any shortening of one leg and speaking generally Sir Herbert Waterhouse expressed the opinion that Mrs. Douglas had had nothing the matter with her calling for special treatment.

Mr. Frank Romer M.R.C.S. who said he had specialized in what was known as manipulative surgery expressed the opinion that the bones stated to have been moved by the plaintiff could not be moved. He concurred in the evidence given by Sir Herbert Waterhouse.

Dr. W. J. C. Keats of Wanstead who also agreed with what Sir Herbert Waterhouse had said stated that he had been Mr. Douglas's regular medical attendant and had examined her in March 1916. He thought the osteopathic treatment she had been receiving was wholly useless and that she had derived no benefit from it.

The defendant (Mr. Douglas) in his evidence said that he informed the plaintiff by letter in June that he had stopped his wife's visits to him because he was not satisfied with the treatment she had been receiving. After two or three visits she seemed to be a little better but subsequently became worse.

Mrs. Douglas who also gave evidence said that she went to plaintiff on the recommendation of a friend to get rid of faceache and he told her he could make her better. She felt better after two or three visits to him in April but after that her condition became worse and she stopped going to him because he was doing her no good. She had complained to plaintiff that his treatment was rather drastic and that once she nearly fainted on her return home.

In Honour and that he was satisfied that the treatment given by Mr. Macnaghten to Mrs. Douglas could not have achieved any beneficial results and he had come to the conclusion that the services rendered by him were wholly useless. He accordingly gave judgement for the defendant with costs.

## Universities and Colleges

### UNIVERSITY OF OXFORD

At a congregation held on October 20th the following medical degrees were conferred:

B.M.—C. L. Cope P. C. MacLennan

### UNIVERSITY OF CAMBRIDGE

Mr. FRANK CLARKE CVO, formerly an exhibitor of the college and assistant demonstrator of anatomy in the University has been elected an honorary fellow of Downing College. He graduated M.B. Lond. in 1881 M.D. in 1885 and became F.R.C.S. L.S. in 1894. He is consulting surgeon to the Central London Ophthalmic Hospital and has been President of the Ophthalmological Section of the Royal Society of Medicine.

The Raymond Horton Smith Prize for the best M.D. thesis during the past academic year has been awarded to V. B. Wilesworth M.A. B.Ch. of Cairns, *Proxime accessit*, A. L. Roche M.A., M.D., M.Ch., of Manchester.

### UNIVERSITY OF EDINBURGH

At a graduation ceremony on October 22nd the Diploma in Public Health was conferred upon the following:

W. T. de Silva E. F. Bell R. A. Macdonald D. F. Macfiver M. C. J. Macleod Elizabeth I. M. Whirter

### ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At the meeting of the Royal College of Surgeons of Edinburgh held October 19th Dr. Alexander Miles was elected president for the ensuing year. Dr. A. Logan, former vice president and Mr. John William Struthers F.R.C.S. Ed. secretary and treasurer.

The following twenty-five successful candidates out of ninety-three entered having passed the requisite examinations were admitted Fellows:

J. M. D. Watt W. A. Blomfield W. M. Brown J. H. Conch A. F. W. da Costa H. Da C. F. Duncan Caroline A. Elliott G. M. Irvine W. H. G. M. Lill H. C. Lorry R. R. Macintosh H. Macpherson R. B. Martin R. S. Melville A. J. Murray J. S. Ramsay R. K. Ran L. J. Ryan R. V. S. Selvadurai M. A. Swan T. E. Stoker B. M. G. Thomas J. Troup J. V. Young

### UNIVERSITY OF DUBLIN

#### SCHOOL OF PHYSIC TRINITY COLLEGE

The following candidates have been approved at the examination indicated:

**FINAL EXAMINATION—Part I Materia Medica and Therapeutics Medical Jurisprudence and Hygiene Pathology and Bacteriology**

**D.P.H.—Part II Sanitation Public Health Administration Hygiene and Epidemiology Sanitary Law and Vital Statistics** Kathleen M. Kennedy M. Halligan Sarah M. Colahan Brenda M. Young

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

Calendar for 1927-28

The College Calendar for the current year includes as usual a report of the proceedings of Council during the past twelve months. A large part of the matters recorded therein have formed the subject of notes in this column from time to time.

In regard to the primary Fellowship examination it has been decided that no alteration shall be made at present in the subjects of this examination and that no exemptions of any kind shall be granted. The Council has however, resolved that it is desirable to send examiners to the Dominions to conduct a primary examination for the Fellowship of the same standard as the examination in this country on conditions to be hereafter determined provided that satisfactory arrangements can be made. To this end negotiations with the proper authorities in Canada have been authorized. The fees for admission in the diploma of Fellowship have been revised. In future, besides the examination fees a member will pay 10 guineas on admission and a non-member 30 guineas. Under the authority given by the recently granted Supplemental Charter the Court of Examiners has been increased from ten members to twelve.

In the period under review 60 diplomas of Fellowship were issued including one to a medical woman, 700 diplomas of Membership including 117 to women and 129 licences in dental surgery including 12 to women. The following diplomas were granted jointly with the Royal College of Physicians: Public Health 53, Tropical Medicine and Hygiene 49, Ophthalmic Medicine and Surgery, 40 Psychological Medicine 22 Laryngology and Otology 19.

The subject of the Jacksonian Prize for 1923 is the surgical treatment of pulmonary tuberculosis. The prize for 1925 was awarded to Mr. E. Miles Atkinson.

Mr. G. Buckston Browne has given a sum of £5,000 the interest from which is to be expended in providing an annual dinner on the College Premises for Fellows and Members and such others as

the President and Council may wish to invite, at least half the guests invited to be Members of the College.

The report on the work of the Museum records that the greatly extended odontological collection was opened by the President on May 23rd, Sir Berkeley Moynihan's speech was published in full in our issue of May 28th, p 978. In January, on the initiative of the President, a large party of medical students from Leeds spent a day examining the contents of the Museum, and the hope is expressed that students of other provincial universities and medical schools may be induced to follow this example. During the year rapid progress has been made in the laborious work of preparing a new descriptive catalogue.

The library report states that the librarian is now engaged upon the compilation of a catalogue of all the manuscripts in the library, including many bearing on the history of the Museum and College at large. The "Lives of the Fellows" have been kept up to date.

Notice is given that the annual meeting of Fellows and Members will be held at the College Lincoln's Inn Fields, on Thursday, November 17th, at 3 o'clock, when the Council's report will be presented.

## ROYAL COLLEGE OF PHYSICIANS OF IRELAND

### LECTION OF OFFICERS AND FELLOWS

At the annual stated meeting of the President and Fellows, held on St. Luke's Day, Tuesday, October 18th, the following candidates nominated on July 1st were duly elected Fellows of the College: Geoffrey Bewley, M.D. Dubl (1925), M.R.C.P.I. (1926), Charles Greer, M.R.C.P.I. (1911), Jiwann Ram Maleet, M.R.C.P.I. (1925), James Smelan Quinn, M.D. Dubl (1925), M.R.C.P.I. (1925).

Dr. William Arthur Winter, M.D. Dubl, D.P.H., was elected President of the College in succession to Professor T. H. Wilson.

The following Fellows were elected Censors of the College: Medicine, Dr. Callaghan, Dr. Syngé; Medical Jurisprudence and Hygiene, Dr. Bigger; Midwifery, Dr. Solomons.

The President appointed Dr. Solomons a Vice President of the College.

The election of officers resulted as follows: Representative of the General Medical Council, Sir John Moore; Treasurer, Dr. Bewley; Registrar, Dr. Kilkpatrick; Librarian, Mr. R. Phelps; Dr. John Spence was elected Deputy for the King's Professor of Materia Medica and Pharmacy to act as Physician at St. Patrick's Hospital.

As representatives of the College on the Committee of Management under the Conjoint Examination Scheme the following Fellows were elected: Dr. Walter Smith, Sir John Moore, Dr. Kilkpatrick.

### ANNUAL DINNER

In the evening the annual St. Luke's Day dinner was held, when the newly elected president was in the chair. A large number of guests were entertained, including the Chief Justice, the Provost of Trinity College, the Presidents of the Royal College of Surgeons in Ireland, of the Royal Academy of Medicine, of the Incorporated Law Society, of the Royal Hibernian Academy, of the Royal Society of Architects, and of the Chamber of Commerce, as well as the Dean of St. Patrick's, the Very Rev. Father Finlay, and the Archdeacon of Dublin. A telegram of salutation was sent to the Royal College of Physicians of London and duly acknowledged.

## CONJOINT BOARD IN SCOTLAND

The following candidates have been approved at the examination indicated:

**FINAL EXAMINATION**—Out of 105 candidates entered the following have passed: M. M. Wright, F. A. Buttner, T. Lotter, M. A. H. Gohar, K. R. Bali, G. D. Roche, M. M. Farhah, K. R. Trembath, P. M. E. Logan, S. Jurawan, T. B. Dobson, S. K. Ponniah, R. O. Adhikari, J. S. T. Isbister, G. M. Johnson, C. D. C. Golding, A. A. Hase, S. Sivalingam, R. Kandiah, S. C. Lovett, Bulankulame, A. W. Green, B. I. Campbell, W. Jackson, T. W. A. Wilson, W. T. A. Peace, T. C. A. B. Anna.

The following have passed in the subjects indicated:

**Medicine**: E. S. R. Menon, M. R. Ramjohn, A. B. Anderson, H. F. N. Slane, R. G. Paranjape, B. J. S. S. Chelliah, V. Sanetamby, J. E. Felix, **Surgery**: D. A. Hoid, F. H. D. J. Maslamm, M. Kier, W. Wallace, **Midwifery**: D. A. Hoid, C. A. Munro, Agnes Donald, son, E. S. R. Menon, S. S. Nagi, A. B. Anderson, H. F. N. Slane, S. Chelliah, **Health**: G. Henderson, N. J. W. J. de Villiers, R. G. Paranjape.

hundreds of certificates were issued.

## SECOND ATTACK

H. J. Haremont, B. D. Jain, D. I. Jones, I am obliged to you for the information given in your issue of 11th inst. regarding the case of my patient, Mr. J. H. Jones, who has been suffering from a severe attack of the disease. I have been unable to find any other cases of the disease, and I am therefore very much interested in the case. I have been unable to find any other cases of the disease, and I am therefore very much interested in the case. I have been unable to find any other cases of the disease, and I am therefore very much interested in the case.

SOCIETY. The following candidates have been approved at the examination indicated: H. J. Haremont, B. D. Jain, D. I. Jones, I am obliged to you for the information given in your issue of 11th inst. regarding the case of my patient, Mr. J. H. Jones, who has been suffering from a severe attack of the disease. I have been unable to find any other cases of the disease, and I am therefore very much interested in the case. I have been unable to find any other cases of the disease, and I am therefore very much interested in the case.

was granted to Messrs R. P. Charles, G. H. Haidaker, B. D. Jain, G. C. Rhys, and V. R. Smith.

## Obituary

Dr. DAVID RUTHERFORD ADAMS, physician to the Whitechapel Tuberculosis Hospital, Toorquay, and pathologist to the Toorquay Hospital, died of pneumonia in a nursing home in Toorquay on October 17th at the early age of 40. He graduated M.B., Ch.B. Glasg. in 1910, and M.D. with commendation four years later. He had held resident appointments in the Glasgow Royal Infirmary and in the City Fever Hospitals, and had been engaged for a time in pathological work in the Western Asylum Research Institute. After a period as assistant surgeon to the Kilmaronock Infirmary, Arishie, he held a commission in the R.A.M.C. and served on the Salonika and Italian fronts. On his return from the war he began practice in Toorquay, first in partnership with Dr. Anbosa Spong and later with Dr. D. G. Riddell, his professional ability and social gifts rendered him very popular. He is survived by a widow and four children.

Dr. JOHN RUDD LEFSON, mayor of Twickenham, died on October 23rd, in his 74th year. He received his medical education at St. Thomas's and Edinburgh, and also studied in Vienna and Berlin. As a student he worked in Lister's wards in the Edinburgh Royal Infirmary, and his book *Wards as I Knew Him*, was reviewed in our columns on April 16th, 1927 (p. 728). He obtained the M.R.C.S. in 1875, and graduated M.B., Ch.B. in the following year, proceeding M.D. in 1882. He had held the appointments of senior consulting physician to the St. John's Hospital, Twickenham, and consulting physician to the Metropolitan and City Police Orphanage. He was a divisional surgeon of the St. John Ambulance Brigade, and a Fellow of the Royal Astronomical, Royal Microscopical, Geological, and Linnæan Societies. Dr. Leeson retired from active medical work several years ago, and since then had devoted his life to public work in Twickenham, becoming its first mayor when this town was incorporated as a borough last year. He was a Justice of the Peace for the county of Middlesex.

## Medical News.

THE following appointments made to the staff of the London School of Hygiene and Tropical Medicine took effect on October 1st. Mr. Reginald Lovell, M.R.C.V.S., to be research assistant in comparative pathology, Mrs. W. M. Smith, M.A., to be demonstrator in bacteriology, Miss H. M. Woods, F.S.S., to be assistant lecturer in the division of epidemiology and vital statistics. Mr. W. Rees Wright, M.Sc., has been appointed to a temporary research post, to continue Dr. P. A. Buxton's investigations on the biology of *Stegomyia*.

As already announced, a dinner to celebrate the incorporation of the British Institute of Radiology with the Röntgen Society will be held at the Hotel Great Central, Marylebone Road, on Friday, November 18th, with Sir Humphry Rolleston in the chair. As was made quite clear in a paragraph published on October 15th (p. 697) the two societies have amalgamated on equal terms. The present officers of the British Institute of Radiology whose names were mentioned in the paragraph are retiring, and will be replaced by officers to be elected at a general meeting on November 17th of members of the new society formed by the amalgamation.

THE Woolwich and District War Memorial Hospital at Shooters' Hill will be formally opened on Wednesday next, November 2nd, at 2.45 p.m., by H.R.H. the Duke of York, who will be accompanied by the Duchess of York. A preliminary account of the new buildings appeared in our issue of May 14th, p. 892.

THE National Association for the Prevention of Infant Mortality and for the Welfare of Infancy has arranged a course of lectures on the hygiene of married life and parenthood (for married people only) to be given in the Lecture Hall, Carnegie House, 117, Piccadilly, on Wednesday, November 2nd to December 7th, at 8.30 p.m. The subjects and lecturers are as follows: Physiology of reproductive organs, Professor Winifred Cullis; hygiene of pregnancy—from the mother's and the father's point of view, Lady Brett; how a new life begins and what it owes to its ancestry, Dr. J. S. Fairbairn; contraception, Dr. L.

Pitchard the effect of discipline on mental development Dr O W Kimmis sterility by Professor Louise Vellroy Fees 7s 6d for the course for one person, or 10s 6d for husband and wife 1s 6d for a single lecture Tickets may be had from the secretary of the Association, 117, Piccadilly, W 1

THE Fellowship of Medicine announces that Mr Lawrence Abel will deliver a lecture on points in the diagnosis and treatment of pyuria at the Medical Society, 11, Chandos Street, Cavendish Square, on October 31st at 5 p.m. On the same afternoon Dr Donald Paterson will give a medical demonstration at the Great Ormond Street Hospital at 2.30 p.m. and Mr Bright Banister a surgical demonstration at the Chelsea Hospital for Women at 2 p.m. The lecture and demonstrations are free to medical practitioners. Two courses begin on October 31st: one lasting four weeks, will be held at the London Local Hospital, and the other, a five afternoon course for general practitioners, will continue at the Hampstead General Hospital for two weeks. From November 7th to 12th the Hospital for Diseases of the Chest Brompton will provide a comprehensive course, and there will be a clinical course at St Peter's Hospital from November 14th to 25th with a series of lectures on diseases of the urinary tract. From November 14th to December 3rd a course in medicine, surgery, and gynaecology will be held at the Royal Waterloo Hospital. From November 21st to December 17th the West End Hospital for Nervous Diseases will give a series of clinical demonstrations upon selected cases in the out-patient department in Welbeck Street daily at 5 p.m. and there will be a course for general practitioners at the London Temperance Hospital during the two weeks following November 21st from 4.30 to 6 p.m. A course in proctology at St Mark's Hospital will extend from November 28th to December 3rd. Copies of syllabuses of these courses and of the *Post graduate Medical Journal* are obtainable from the Secretary of the Fellowship of Medicine, 1, Wimpole Street W 1.

A COURSE of post graduate lectures at Ancoats Hospital, Manchester opened on Thursday last when Mr H E Hughes discussed the early diagnosis of intestinal obstruction. On November 10th he will deal with gall stones and on November 24th with the diagnosis and treatment of common ailments of the rectum. On November 3rd Dr Kletz will discuss diarrhoea and on November 17th the medical treatment of peptic ulcer. The lectures which begin at 4.15 p.m. are open without fee to medical practitioners and senior students. Tea will be served at 3.45 p.m.

DURING November a series of lecture demonstrations will be given twice a week at 4.30 p.m. at the Wes London Hospital Post Graduate College, free to medical practitioners. On November 1st Dr Sydney Owen will deal with infant feeding and on the 8th with the heart in childhood. On November 4th Mr Neil Sinclair will speak on gall stones, and on the 16th Dr G B Dowling will discuss the preservation of a youthful skin. Mr Tyrrell Gray will give two lectures on gastric and duodenal ulcer the first being on the 17th and the second on the 24th. On November 22nd Dr Sent Pinchin will speak on cardiac irregularities, and on the 30th Dr Carter Braine will consider the therapeutic application of x-rays. A staff consultation will be held on November 11th, at 5 p.m., in the massage department.

THE Prince of Wales opened the new extension of the Boscombe Branch of the Royal Victoria and West Hants Hospital on October 19th. He named the new ward, which has been specially adapted for sunshine treatment, as the Prince of Wales Ward.

THE annual dinner of the Chelsea Clinical Society was held on October 25th. Dr L D Bailey, M.C., the president, took the chair and there was a good attendance of members. The toast of "The Society" was proposed by Alderman J E Jefferson Hogg, ex-mayor of Chelsea, and the president in acknowledging it referred to the flourishing state of this fraternity which was now in its twenty-ninth year. The membership was 158 and the standard of interest of the meetings was well maintained. The toast of "Kindred Societies" was proposed by Dr F J McCann in a humorous speech, and Mr Mortimer Woolf, president of the Hunterian Society, replied. Mr Ivor Back added to his reputation in a witty speech, proposing the health of "The Gneiss" replies being made by Sir William Osler, B.A., who showed that brevity could be the soul of wit, Mr Leonard Huxley, LL.D., Mr J Hugh Edwards, M.P., who indicated with many jests and epigrams the value of the medical profession to the nation as a whole and the Hon Alan Hood, who spoke of the part played by medical practitioners in building up the Empire overseas. The toast of "The President" was proposed by Dr Ernest Young and in his reply Dr Bailey referred to the valuable work of the officers of the society including the treasurer, Dr K E Eichenstein, who replied succinctly and effectively.

THE annual dinner of the London Hospital was held at the Trocadero Restaurant on October 20th, when more than 230 old members and guests were present. The chairman, Dr Angus Kennedy, proposing the toast of "The Hospital," referred to the excellence of the training, the remarkable spirit of self-reliance which it encouraged and the devotion to its memory of all its old students. He regretted that the hospital no longer opened its doors to women students. Dr Russell Andrews, proposing the health of the chairman, mentioned that Dr Kennedy's grandfather, father, son, and daughter had all graduated from the London Hospital. He referred to the number of instances in which several generations had passed through the medical school, which afforded sure testimony of their appreciation of the training there.

THE annual autumn meeting of the Society for the Propagation of the Gospel in Foreign Parts was held at the Central Hall, Westminster, on October 25th. The speakers who dealt principally with medical missions included the Bishops of London and Woolwich, Dr D S Bryn Brown of the Yosse Memorial Hospital in North China and Miss B E Corbett a member of the medical mission in Malacca, Straits Settlements.

THE Ministry of Health has issued new regulations replacing the Public Health (pneumonia, malaria, dysentery, etc.) Regulations 1919 which provide for the notification and treatment of certain infectious diseases. Malaria and dysentery, as well as acute primary pneumonia or acute influenza pneumonia, must be notified in the prescribed form irrespective of previous notification. Special provision is made for cases in which malaria has been used for therapeutic purposes such cases occurring in an institution need not be notified, but if the medical practitioner is of opinion that the patient may be regarded as liable to relapses of malaria at the time he is discharged from the institution notification must be sent to the M.O.H. for the district in which the patient proposes to reside. The fee for a notification is, for a private patient 2/6d for a case occurring in the practice of the medical officer of any public body or institution 1s.

DR D W SAMWAYS (Topsnam, Devon) wishes again this year to direct attention to the fact that professional men whose means are limited requiring a change are received into the Home of Rest at Mentone at the charge of 30/- a week for board and lodging. The committee are prepared to give special consideration to the cases of those unable to pay this amount. The stay of each person is limited to three months. The home which is open from November 1st to May 1st is a philanthropic undertaking intended to help professional men who break down temporarily and is therefore useful to medical practitioners of small means, or their professional patients in like cases. Applications should be made to the lady superintendent Miss Goldee or to the honorary physicians, Dr Stanley Peadar or Dr Samways, at Mentone, Alpes Maritime, France.

THE Central Council for Health Education is publishing a monthly periodical entitled *Better Health*, with a view to providing instruction in health matters for the public. The November issue contains an article by Sir George Newman on the relation of food to health and other subjects dealt with include the care of milk in the home, the relation of air and ventilation to health, and the work of the Public Health Department. This publication is well and simply written, and should be of great value in spreading information about the prevention of disease. The annual subscription is 1s 6d, post free and copies may be obtained from the Society of Medical Officers of Health, 35/38 Whitefriars Street E.C.4.

DR RICHARD ARTHUR of Sydney who is Minister of Health in the New South Wales Government formed by Mr Bavin, following the resignation of Mr Lang, the Labour Premier, studied medicine at the University of Edinburgh, where he took the degrees of M.B. Ch.M. in 1888 and M.D. in 1891. He is also M.A. of St Andrews. He is a member of the Legislative Assembly of New South Wales and a member of long standing of the New South Wales Branch of the British Medical Association. He is surgeon to the Ear and Throat Department of the Sydney Hospital.

UNDER the title *Sale of Food and Drugs Acts* a pamphlet has been issued by H.M. Stationery Office at the price of 1s 6d containing extracts from the Annual Report of the Ministry of Health for 1926-27 relating to this subject, together with an abstract of Reports of Public Analysts for the year 1926. The Ministry's Report from which these are taken was noticed in our issue of September 24th (p. 558).

As a large number of applications are received at the Frederick Andrew Convalescent Home, The Manor House, West Malling Kent from persons who are ineligible we are asked to remind possible applicants that the three weeks' free convalescence can only be given after definite mental illness to ladies of better education, who are earning their living in professional or analogous occupations.

On the occasion of the international conference on tabies, recently held in Paris, an international society for micro biology was founded, with Professor Jules Bordet of Brussels as president, and Professor Rudolf Kraus of Vienna, Drs Dujardin de la Riviere and Plotz of Paris as secretaries.

THE annual report for 1926 of Earl Haig's British Legion Appeal Fund includes an account of the British Legion Sanatorium and Settlement at Aylesford, Kent. On March 1st, 1927, there were 142 patients in the sanatorium, and nearly 200 passed through the treatment centre in 1926. The report, which contains detailed information about the organization and results of the sixth annual Poppy Day appeal, may be obtained from the British Legion Appeals Department, 26, Eccleston Square, S W 1.

POST GRADUATE courses on diseases of the heart and circulation will be held in Vienna, from November 28th to December 10th. Further information may be obtained from Dr A. Kronfeld, Porzellangasse 22, Vienna IX.

THE Scottish Board of Health has issued as separate reports the chapters in the annual report of the Board for 1926 relating to (a) encephalitis lethargica, (b) ultra violet ray therapy, and (c) Schick and Dick tests in diphtheria and scarlet fever. The reports have been issued at the nominal price of 2d each, or post free, 2d. Copies can be obtained through any bookseller, or direct from H M Stationery Office, 120, George Street, Edinburgh. The annual report was noticed in our columns of July 9th and 16th, and August 6th.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **British Medical Journal** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **British Medical Journal** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the Journal, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the British Medical Journal are MUSEUM 9861, 9862, 9863, and 9864 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR of the **British Medical Journal**, Atterbury Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Atterbury Westcent, London.

MEDICAL SECRETARY, Atterbury Westcent, London.

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams *Bacillus, Dublin*, telephone 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams *Associate, Edinburgh*, telephone 24361 Edinburgh).

## QUERIES AND ANSWERS

### CANCER AND DIABETES

"C H S" asks for experiences of the occurrence of carcinoma or other malignant disease in patients suffering from diabetes.

### PETIT MAL

"COUNTRY G P" asks for references to recent literature regarding petit mal, and especially as to possible causation by toxic conditions.

### INCOME TAX.

#### Liability of Colonial Medical Officer

"J J B E" is in the Colonial Service and visits the United Kingdom at intervals of from two to two and a half years, but never stays here six months in any one financial year. He has recently acquired the house in which his parents reside and would like to know to what end are directed some questions which he has received from the authorities as to his liability to income tax as a resident in this country.

\* \* \* Residence is a difficult question, which it is impossible to deal with adequately in a brief answer. The points on which the authorities are seeking information appear to be those which might establish that "J J B E" ownership of the house and the financial arrangements between himself and his parents are

such that he has a place of abode in the United Kingdom, which he returns periodically to an extent sufficient to justify the inference that it is one of his places of residence. If this inference is correct then he would be liable to British income tax on that part of his earnings which he receives in this country.

#### Loss Due to Coal Strike

"L R" has been assessed for many years in respect of the earnings of a colliery practice. For the year to April, 1927, he has been assessed on the usual basis of the three previous years, but owing to the strike his expenses exceeded his gross earnings of £75. The inspector of taxes agreed to the deduction of the loss of £75 from the 1926-27 assessment, but says that otherwise it must stand.

\* \* \* That is in accordance with the law, which does not provide for an adjustment of the assessment in such circumstances unless the "average" period or part of it was during a predecessor's tenure of the practice. In fact but for the change in the basis of assessment from the three years' average to the previous year, "L R" would have been chargeable for 1927-28 on from £1,300 to £1,400. If "L R's" earnings return to the former level he will not suffer loss in the long run, though obviously for the time being he has to bear the hardship of finding tax to meet a charge quite out of accord with his earnings for the actual year.

#### Arrears of Liability

"J C G" paid tax in 1921, but has received no assessment since. How far back can the authorities now go, and can he claim an allowance for his housekeeper?

\* \* \* Assessments can now be made for the year commencing April 5th, 1921, and subsequent years. The housekeeper allowance can be claimed only in the special circumstances, looking after children, etc., set out in the notes accompanying the forms of return.

## LETTERS, NOTES, ETC

### Menstrual "Uncleanliness"

DR ROBERT HUTCHISON (London, W.) writes: I am grateful to your correspondents who have replied to the inquiry I made under the above heading. I have also received many private letters on the subject from doctors all over the country which show that the "superstition" referred to is very widespread amongst all classes, and there seems to be no doubt that it has its origin in a "taboo" which dates back long before Biblical times. Several correspondents have directed my attention to the paper by Macht and Lubin, to which Dr Goldmann refers, and which describes the results of the only attempt I have heard of to investigate the subject on scientific lines. I have not yet had time to study the paper myself, but I confess that it would require very strong evidence to convince me that the touch of a menstruating woman can excite decomposition in foods. Meanwhile, I would suggest that the subject is a suitable one for investigation by some of the women members of our profession, for the belief in this "uncleanliness" is evidently real enough to lead to a great deal of practical inconvenience.

### BINOcular VISION

DR KENNETH R. SMITH whose book on *Binoocular Vision* was reviewed in our issue of September 24th (p. 552), writes to explain that his "exerciser for agram" is not intended to be used only with reading matter. He prefers an ordinary pack of cards, which are placed three in a row in the stand. The child sees the centre card with both eyes, the card on the left with one eye, and the card on the right with the other eye. He prefers playing cards to reading matter or pictures.

### MINISTRY OF HEALTH REPORT ON SCARLET FEVER

#### A Correction

DR ALLAN C. PAPSON, Ministry of Health, writes: I have to thank Dr J. A. Milne for drawing attention to an error on page 9 of the recently issued report of the Ministry of Health on scarlet fever. Carbolic lotion 10 per cent. is there referred to instead of carbolic oil, as it should have been written and is written on other pages which described the technique of the Milne treatment, as introduced by his father, the late Dr Peter Milne.

#### A DISCLAIMER

DR A. J. D. CAMERON (Northampton) wishes to dissociate himself from any responsibility for an article in the *Westminster Gazette* of October 14th, headed "Rejuvenation by Fasting," in which his name was mentioned.

## VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 35, 36, 37, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 38 and 39. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 1, 2.

## CHRONIC SEPSIS AS A CAUSE OF MENTAL DISORDER

### 1—RELATION OF FOCAL SEPSIS TO MENTAL DISEASE \*

BY

WILLIAM HUNTER, C.B. M.D. Ed., F.R.C.P. Lond.,  
Hon. LL.D. Ed.  
Consulting Physician to London Fever Hospital and to Charing  
Cross Ho. pital

THE part played by sepsis in producing nervous and mental disorders of all degrees of severity and the degree to which the same can be prevented, checked, or controlled by antisepsis are singularly opportune subjects for discussion on an occasion marking the centenary of the birth of Lister. We are not only commemorating past achievement but inaugurating a new campaign against sepsis in one of the greatest domains of medical diseases—that which bears the ill-omened title of insanity.

It is the first time this subject of sepsis and antisepsis in relation to mental disorders has been before this Association. The types of mental disorders more especially concerned are those that bear the titles of dementia praecox, manic-depressive insanity, paranoid conditions, psychoneurosis, and toxic insanities. These constitute the great proportion of the admissions into our mental hospitals—on an estimate kindly supplied me by our President dementia praecox about 20 per cent, manic-depressive insanity about 50 per cent, paranoid conditions about 10 per cent, psychoneurosis about 5 per cent, and toxic insanities about 15 per cent.

The sepsis with which medicine is concerned is that originally described by me in 1890 under the title of "oral sepsis" and other forms of focal sepsis as a cause of medical diseases—namely the sepsis in teeth, the tonsils, nasopharyngeal nasal sinuses, stomach, intestine, colon, and sometimes elsewhere in the genito-urinary tract—"oral sepsis," "tonsillar sepsis," "nasal sepsis," "septic gastritis," "septic enteritis," "septic colitis," as I then termed the several conditions.

The call I then made (1900) on behalf of this sepsis was that

Sepsis in medicine is playing a greater part in producing medical diseases than it is now doing in surgical affections. A great field of prevention is opened up by the exercise especially of oral antisepsis against oral sepsis the worst and parent source of most other forms of focal sepsis especially that in the tonsils, stomach, intestine, and colon—a field that can be worked in with the most surprisingly satisfactory results by the doctor, the surgeon, the throat, nose, ear, and eye specialist and most of all the dental surgeon.

This call included a special appeal for attention to this sepsis in the realm of nervous disorders as presented in ordinary general practice: its neuritis, its neurasthenias, its mental depressions or its more severe so-called "nervous attacks" or "nervous breakdowns."

One of the conditions I specially called attention to I termed "toxic neuritis." Cases of this kind "open up a new field of inquiry" as regards the possible role of oral sepsis in causing nervous effects such as those I described under the title of "toxic neuritis" (1900).

Now after twenty years I am glad to think that the response to that call has come at last. It has come first of all (1919-23) from the American side at the hands of Dr. Cotton, the director of the New Jersey State Hospital, Trenton, who four years ago (1923) set forth very fully his results before the Royal Medico-Psychological Society at its annual meeting as fully detailed in the *Journal of Mental Science*, October, 1923. Dissatisfied after some fifteen years' experience of mental work with the results obtained he began from 1918 onwards a desperate frontal attack with horse, foot, and artillery—namely medical recognition of the importance of oral and focal sepsis, surgical help for its removal and bacteriological support

for both—on the whole field of the sepsis presented by his cases (1,400 in number), in the teeth, the tonsils, nasal sinuses, stomach, intestine and colon, and the genito-urinary tract, with the result of doubling the number of his discharges, and reducing the average stay in hospital from ten months to three months.

Since then the subject has received steadily increasing attention at the hands of English psychiatrist physicians, and has been before them at three of their annual meetings as a subject of great interest and increasing importance in the treatment of the insane.

As might be expected, the very force of this attack on the problem of sepsis in mental diseases has produced equally strong counterattacks chiefly at the hands of American psychiatrists—especially the studies by Kopeloff, Kober, and Cheney (1922-23) of the New York State Psychiatric Institute. But the net result has been the satisfactory one that, however much they may agree that no importance is to be attached to focal sepsis as a cause of mental disorder, they are all "wholeheartedly in favour of eliminating all focal infection in psychotic patients." That is a great advance on what has hitherto obtained—to wit, that no attention has been paid to it. There the matter at present stands—there is an advance all round.

### SEPSIS IN MEDICINE

If on the present occasion the President and officers of this Section have kindly invited general physicians and surgeons to take part in this discussion, it is owing to the circumstance that the past twenty-five years have furnished a large experience as to the part played by sepsis in general diseases other than nervous or mental—an experience now available in relation to the whole subject of mental disorders. The result of that experience may be best described in the words of others since it was first set forth by me before this Association at its Oxford meeting in 1904 and since so fully confirmed by many others especially William Willcox and Chalmers Watson in this country, Frank Billings, Llewellys Barker, and Charles Mayo in America.

One of the great advances in medicine of the past twenty years. The effects of oral sepsis have been worked out and prove to be so widespread so multiple and frequently so grave as to make us ashamed of our previous blindness to a common source of blood infection staring us in the face all the years. In addition to our knowledge of the first magnitude—Dr. Mitchell Bruce Address in Medicine British Medical Association 1910.

No one circumstance in the last fifteen years that has so changed the aspect of the practice of medicine as the doctrine of focal sepsis—Professor Thayer Johns Hopkins University 1914.

The most interesting chapter in modern medical history profoundly affecting medical and dental practice epoch making in its effects—American dental literature.

A profound and permanent influence on general medicine rendering Lister's hypothesis which governs the practice of surgery at least of equal importance in relation to medicine. Infection in medicine is responsible for a vast number of diseases—a fact that has received far less attention than it ought to have had. The immediate ravages of oral sepsis may prove serious enough but the remote complications seemingly unrelated to their true cause are a grave menace both to health and life—Sir Berkeley Moynihan 1927.

These appraisements may serve to indicate at once the chief site (the teeth), the apparently negligible character but nevertheless the actual supreme importance of the fact of sepsis with which medicine as distinct from surgery is specially concerned, with which also, however the surgeon has learnt to be equally concerned as a great potential and actual source of much of the septic infection in his surgical cases.

The sepsis with which the surgeon has been concerned is something obvious, manifested by recognizable effects such as inflammation, suppuration, death of tissue, fever, and septicaemia—common effects producible by a large range of organisms, but chiefly those of the staphylococcal and streptococcal groups, or, in the case of the alimentary tract, the *B. coli* group. But he is not specially interested in the character of the organisms; his whole concern is that no organisms of any kind invade his wounds in the course of his operations.

But the features of the sepsis operating in medicine are of a different and more complex character. Its foci are small, hidden, chronic, and cause generally no local effects

\* The opening paper to a discussion in the Section of Mental Diseases at the Annual Meeting of the British Medical Association, Edinburgh, 1927.

This case illustrates, according to its recorder, the effect of impacted third molars in producing these conditions.

Table showing Incidence and Sites of Focal Sepsis treated successfully in 100 Male and 100 Female Patients (Dr Cotton)

Mental Disorder	Total		Teeth		Tonsils		Gas ric		Vaccine		Vesiculo- tomy	Cervix	Colon	
	Male	Female	Male	Female	Male	Female	Male	Female	Male	Female	Male	Female	Male	Female
Manic-depressive in acute	49	65	49	60	39	47	41	50	41	45	1	8	—	9
Dementia praecox	18	8	18	8	13	7	13	7	13	7	—	5	—	2
Paranoid condition	15	9	15	9	11	6	14	5	14	5	—	1	1	1
Psychoneurosis	7	10	7	10	7	6	6	7	6	6	1	2	—	—
Toxic psychosis	11	7	11	7	6	7	9	7	10	7	—	4	—	1
Totals	100	100	100	100	76	73	83	76	81	71	2	20	1	13

mental states which so closely resemble dementia praecox. For such teeth are always, in his experience, found to be infected. It shows how the removal of some particular focus of infection such as the tonsils in this case, may fail to improve the mental condition, and the necessity in such an eventuality for seeking for other possible foci—in this case the impacted teeth. It also indicates the difficulties presented to the full investigation of patients owing to their excited state, and their refusal to allow any examination of their mouths or throats radiographically or otherwise.

The problem is whether to wait for weeks, possibly months, till the violence of the mental symptoms subsides or lessens, or, on the other hand to face what appears to be the risks and carry out operations such as dental extractions while the patient is still violent.

Every case of this kind must be considered on its own peculiar features of urgency and severity. It is a matter which specially requires the judgement of the physician in charge of the case. I may give my own experience that any such apparent risks can be safely run.

The existence and possible importance of impacted and unerupted teeth in mental cases, here noted by Dr Cotton are in my judgement observations of interest in revealing the earlier dental history of such cases. Thus in 120 cases recorded by Kopeloff and his fellow workers (1923) I find that as many as 15 cases (or 1 in 8) showed such teeth to the number of no fewer than 49, an average of 3 such teeth to each case. If these teeth become infected, as in cases of long-standing and severe sepsis they are most likely to be, the neurotoxic action of such sepsis is enclosed in the alveolus of the jaws is likely to be very severe, as in the case above recorded.

The existence of such teeth in 1 in 8 cases of dementia praecox and manic-depressive insanity emphasizes in my opinion the importance of the earlier dental history of all cases of this character, especially in young people and young adolescents. I have had cases in which I have been able to trace back a continual history of severe dental infection from the time of dentition at the age of 2 onwards.

In my judgement the dental history and the high degree of sepsis present in the last mentioned case would probably be found, if fully investigated, to represent approximately the dental history and degrees of sepsis of most cases of the severe and prognostically grave mental disorders affecting juveniles or young adolescents. I draw special attention to the matter as one worthy of investigation and inquiry in every case of this character.

If, as I am satisfied from my own clinical experience as a physician is the case, this widespread septic infection is also in particular instances causing direct and various psychotic effects, the title from now onwards that would, in my judgement best connote this form of psychosis would be the one I would now suggest of 'septic psychosis'.

This commonest form of psychosis produced by long-standing chronic septic infection, exists sometimes alone, but more frequently along with and complicating other forms of psychosis intensifying and aggravating the more special mental features belonging to these latter psychoses. The extent to which it is present in any case can only be determined by removing it, and the best hope that any psychotic patient can have about his trouble is that it may prove

to be largely or possibly entirely, of the nature of a septic psychosis, and therefore one which may possibly be removed by removal of the septic foci underlying it.

As regards the possible importance of this 'septic psychosis' in psychiatry perhaps the most judicious opinion is that pronounced by Dr Adolf Meyer, professor of psychiatry in the Johns Hopkins University.

The evaluation of focal infections is an outstanding contribution of twentieth century medicine. If means could be made available to remove such focal infections in all mental cases psychiatrists would make another large contribution of importance far beyond its own special sphere of mental hygiene, and relieve a group of patients of one of the insidious suppressing influences taxing humanity, thus offering a free field to work with the many other features which are bound to play a part. In dealing with it I would only make one plea. Do not let it go forth that sepsis is the cause of all insanity, for that is the sort of statement that always puts the clock back. Let us be content to know on evidence that a new era has been opened up for the prevention or cure of many cases of mental disorder, by surgical attention to septic conditions.

#### INCIDENCE AND SITES OF FOCAL SEPSIS

The incidence and sites of the focal sepsis found in mental disorders are well brought out in the above table of 200 cases treated successfully by Dr Cotton, and found afterwards on visit to have remained well.

In his experience in the case of men the teeth were found infected in all cases, and in every form of psychosis, the tonsils in 76 per cent of cases, the stomach in 83 per cent (all of them requiring treatment with vaccines) the seminal vesicles in 2 per cent, and serious lesions of the colon in 10 per cent. In the case of women, the teeth were found septic in all cases, the tonsils in 73 per cent, the stomach in 76 per cent (requiring treatment with vaccines in 71 per cent), the cervix in 80 per cent, and serious lesions of the colon in about 30 per cent.

As regards the incidence in different forms of psychosis there was little or no difference between them in males, but in women the colon was operated on in 13 per cent of cases as compared with only 1 per cent in males, 9 of the cases being among 66 cases of manic depressive insanity.

Interesting data regarding the incidence and seats of focal sepsis are also supplied by Dr Graves, the director of Rubery Hill and Hollymoor Mental Hospitals of the Birmingham Corporation. The first of the hospitals in this country to supply data of this character.

No of Cases	Teeth	Tonsils	Nose	Ear	Cervix
270	230	—	—	—	—
253	193	—	—	—	—
123	—	43	18	39	—
29	—	104	20	105	—
139	—	—	—	—	20

These figures yield the following incidence of septic foci in different seats

Oral sepsis	76 per cent
Tonsillar sepsis	40 "
Nasal sinusitis	10 "
Ear	39 "
Cervix uteri	71 "

The figures show the widespread character of the sepsis present in the mental patient.

The percentage incidences for the teeth and tonsils (76 and 40) are considerably lower than those found by Dr. Cotton (100 and 76) respectively, but they are interesting in confirming the high incidence of cervix infection—namely, in 71 per cent of women. They draw attention to the incidence of nasal sinusitis in at least 10 per cent of cases, but most of all to the high incidence of ear sepsis in 39 per cent of cases.

The relative importance of the various seats of focal sepsis, I would point out, is not dependent on the relative incidence of such infection in the various seats—teeth, tonsils, nose, cervix, etc., it is determined far more by the amount of sepsis which may be harboured in each seat, and by the conditions favouring its chronicity and by its virulence. In this relation oral sepsis (dental sepsis) is by far the most important, for the number of foci which the teeth may harbour depends not only on the number of septic teeth which may be present, but also on the number of septic sockets connected with these teeth. Thus the presence of four septic molars each with three roots means the existence of twelve septic foci, and may thus be the equivalent of eight incisors and four canines which have only one root each.

I have been much impressed by the degree of infection in the sockets of infected teeth in many cases, cultures which I myself have taken with extreme precautions from the apices of the teeth immediately on their withdrawal, and planted on sloped agar tubes, growing hundreds of colonies of staphylococci sometimes in almost pure culture (90 per cent).

The degree of oral sepsis cannot be expressed in terms of "infected teeth" as some observers do (Kopeloff, 1923). It must have regard to all the other conditions present—of septic gingivitis, tartar deposit, ulceration and pocketing, pyorrhoea, of periodontitis and osteitis shown by recession of gums or looseness of teeth, or by thickening of alveolar margins, number of carious or necrosed teeth, number of devitalized teeth (nerves destroyed), number of teeth with gold caps or porcelain crowns, gold bridges (a very potent form of sepsis, especially in regard to its neurotoxic effects), and finally, to conditions revealed by radiographs of apical abscesses and granulomata, of buried roots, of impacted or unerupted teeth.

When regard is had to all these conditions, the ordinary degrees of oral sepsis usually found—slight, moderate, or severe (1°, 2°, 3°), as I am accustomed to designate them—will often, in my experience, be found to be so severe (especially in mental cases) that it can only be expressed by degrees varying from 5° up to 10°.

The amount of infection elicited by all these various conditions is far greater than anything ever found in connection with infected tonsils, and also far more virulent, since it is all in connection with bone tissue, which always enhances the virulence of a septic infection.

It is this latter circumstance that adds to the virulence of nasal sinusitis and ear infection, which also can be very severe in mental cases.

#### NEW ERA OF ANTISEPTIC IN MENTAL DISORDERS

In the foregoing I have endeavoured to give a glimpse of the character of this subject of sepsis in relation to mental disorders, from the point of view of a general physician well acquainted with the characters and potentialities of the sepsis concerned—rather than from that of the psychiatrist physician to whom many other questions of interest arise.

The same applies to matters of surgical interest arising out of this new aspect of mental disorders: the work required from the dental surgeon, from the radiographer, from the throat, nose, and ear surgeon, from the abdominal surgeon in connection with the surgery of the intestine and colon, from the genito-urinary surgeon in connection

with the prostate and seminal vesicles, and lastly from the gynaecological surgeon. I see no person who the help of the surgeon in dealing with conditions of sepsis present in mental patients should not be warmly welcomed, in the hope of restoring sanity to a disordered mind, just as readily as it is placed at the disposal of any other class of some accident might require such help.

Discovery of the part played by sepsis in mental disorders introduces an entirely new era into the whole subject of the nature of many of these disorders, and the possibility of controlling and preventing them. They make clear, in my judgement, that it is septic infection that underlies many mental disorders hitherto regarded as denoting a foreshadowing permanent damage, or contributes to the severity of such disorders even when permanent damage has been done.

This "septic psychosis"—as I would now term it—is produced by the action of toxins derived from small and apparently insignificant septic foci, chiefly in the teeth and tonsils and elsewhere. On the removal of these the whole mental disorder may be profoundly affected, and may in many cases be made to disappear. By the removal of such septic foci with the attendant septic psychosis the control of mental disorder and insanity in many of its forms and manifestations is rendered possible to a degree never before attainable. The degree of disorder may be of such a character and duration—for example, that presented in dementia praecox, or in severe manic depressive insanity—as to suggest permanent damage to the higher brain centres, and to appear, therefore, incapable of being influenced by the removal of slight septic foci. But the clinical facts show that this is not the case, and the extent to which the degree of sepsis present in each case is affecting the character and degree of the mental features of the case in causing a "septic psychosis" can only be determined by the removal of that sepsis.

The removal of the sepsis in all cases of mental disorder and insanity is therefore called for as a matter of urgency and as a first measure of treatment in every case. The amount of chronic sepsis present among the mental patients who to the number of 133,000 and more occupy the mental hospitals and asylums of this country is far greater than that to be found in any other group of inmates of our hospitals. The removal of that sepsis in these cases is imperative to a degree, as the first and most important measure of treatment applied to them. For in these cases the evidence already available makes it clear that however much ordinary people in health may be able to resist, and do successfully resist, the deleterious action of the varying degrees of similar sepsis which they carry, the sufferer from mental disorder cannot afford to have any such sepsis unremoved. He is playing for the highest stakes—the preservation of his brain power and his sanity. He can run no risks. And inasmuch as in his case the control of his illness is out of his hands, it is all the more incumbent that every possible measure of treatment should be available and should be applied for his benefit.

Each mental hospital should therefore be as fully and as well equipped for surgical work as it has hitherto been for medical or nursing care. Its staff should include a resident and visiting surgeons concerned with dental, throat, nose, and ear, abdominal and gynaecological surgery. This involves the provision of a fully equipped dental department and surgical theatre for every mental hospital, with a resident dental surgeon and anaesthetist, and a visiting staff of a general surgeon, and throat, nose, and ear specialists, with the necessary radiographic and biological departments. In making this provision all public authorities will, I feel sure, have the whole-hearted approval of the public, rightly concerned for the mental health of more than for any other class of sufferers.

The possible standard of increased relief which can be expected of this class may receive its full effect if the chances of recovery may be doubled, that the duration of their stay in hospital may be materially reduced, and that on discharge the chances of remaining well, both physically and mentally, will be greatly improved by the removal of the sepsis which they previously carried, if that removal is carried out at the first onset of the trouble before permanent damage is done.

But it is in the realm of prevention that this new application of antiseptics will find its greatest triumph—namely, the cutting short of all sorts and degrees of nervous and mental disturbances that in most cases precede and herald the onset of the graver mental disorders.

## II.—RELATION OF ABERRANT MENTAL STATES TO ORGANIC DISEASE

BY

SIR BERKELEY MOYNIHAN, Bt. M.S.

President of the Royal College of Surgeons of England

In the month of April we celebrated the centenary of Lister and in a week of devotion to his illustrious memory we recalled the incomparable services rendered by him to the cause of humanity. We heard once again from the lips of men representing all the civilized countries, each of them a spokesman of high distinction, that Lister by his researches had changed the whole scope and practice of surgery. So long as men shall live and suffer, to be rescued from their suffering by the art of the surgeon, so long must the hand of Lister be there to heal them, for the principles laid down by the master are eternal.

Among the multitude of voices which bore eloquent testimony to the immortal labours of Lister, there was one only which witnessed to the truth that the scope of his doctrine spread beyond the bounds of surgery and must be held to include the whole province of medicine including research.

The bent of Lister's mind towards biology was soon observed. Many of his early experiments seemed to have little direct bearing upon the craft of the surgeon. Yet he had derived from John Hunter the belief that the beginning of surgery is a knowledge of inflammation and

in studying this process he was making his mind ready for the new observations and deductions which Pasteur was soon to make plain to the world. Pasteur's work had been published some years before, and had been accessible to all. When Lister was handed Pasteur's original paper by the professor of chemistry at Glasgow he alone of all who read it was able to realize at once the direct relevance of this new doctrine decided and deemed by high authority to the science and practice of surgery. It is as clear an illustration as was ever given of the need which lies upon us all to keep our minds open to new truths, expectant of them competent to test and to apply them. Such truths may be born, will, in fact, in the near future almost certainly be born, in the minds of those not directly engaged in the service of surgery.

We speak of Lister's work in its relation to surgery, and might attribute to him the almost incredible changes which have come over our own art. But the eternal principles established by Lister have an effect upon all branches of medicine. And it may truthfully be claimed that the adventures of the surgeon have consumed and illustrated the truth which we owe to William Hunter alone—that infection plays a large part, often indeed the chief or the only part, in the inauguration of many of the diseases still within the province of the physician or the alienist. The thesis developed by him in a series of papers which display both remarkable originality of thought and careful and patient observation, concerns the part played by slight and continuously overlooked forms of sepsis in causing distant and apparently unconnected disorders often serious and disabling and not seldom, in their full career the cause of death. For over twenty years William Hunter pursued his way and preached his doctrine, unregarded, discredited, or denied. For years he was a voice crying in the wilderness. There was once a voice crying in the wilderness which changed the face of the world, and built the world anew on foundations which can never be shaken. William Hunter's contribution to direct research is, in my judgement, the most significant of any conducted in the last generation. Of the truth of his teaching there is not the slightest doubt. Thanks to him we recognize now the grave importance, the causal significance of small and often concealed areas of septic infection—in the tonsil, the pharynx, the nasal sinuses, the prostate, the cervix uteri, the appendix, the uterine appendages, the gall bladder and other organs. Hunter's earlier conclusions had reference to the graver forms of anæmia and he was the first to point out the causative associations of oral sepsis with pernicious anæmia. We are now learning the full truth of his work. We are quick to recognize the dependence of anæmia, of glandular diseases, of certain obscure fevers of various forms of "rheumatic" affections, of gastric and intestinal disorders, of severe affections of the kidney, and of many affections of the nervous system—from neuritis to functional nervous and mental diseases—of perhaps all forms of cardiac diseases, upon "focal sepsis." In the days before Lister so my teachers told me, the surgeon would look with apprehension for a bluish round, a recent wound, and would lay his fingers upon the sterno-clavicular articulation to discover whether the joint was tender. Paemia, which had wasted the joints of the limbs in a riot of rapid disorganization, was the most dreaded of all the consequences of wound infection. It was not infrequent for the sterno-clavicular articulation to be the first of all the joints to be affected. Rheumatoid arthritis is paemia moving slowly.

My acquaintance with the mental disorders consequent upon infection is not enough to entitle me to speak with authority in the least degree comparable with that of the distinguished alienists who will contribute to this discussion. But no one who has been attracted to the study of the mind's working in health (if we may for the moment assume the existence of such a state) and in disease can have failed to notice the close relationship of aberrant mental states to organic diseases, especially those owing an infective origin.

My own attention was first attracted to this subject many years ago when gastric surgery was in its early days. It was no uncommon experience then to operate

upon patients who had for many years lain under the accusation of being "neurotic." For long periods of time they had complained of pain after food, they had in consequence reduced the amount of food taken, restricting themselves to a diet the ingredients of which were readily absorbed or easily propelled, they were often wasted, querulous, ill tempered, hard to live with, and their social reactions were not improved by the repeated denial of the reality of their sufferings. Yet when an operation was performed, in advanced condition of organic disease of the stomach, for example, was discovered, and by degrees it became realized that the patients had good cause for the complaints which they made. The existence of organic disease in those called "neurosthenic" was often so certain, though obscure, that I endeavored to impress upon students that the literal translation of the word "neurosis" was "I don't know." Neurosis was the word which covered (and still covers?) a great deal of ignorance. This experience does not indicate merely a mistake in diagnosis by a succession of observers. For the state of the patients fully justified their inclusion among a group of victims of functional psychoses. The point is rather that continuous physical illness, infective in origin, leading to gross organic disease, long unrecognized, has produced a real mental disorder which was regarded as primary, and therefore unrelated to any physical change. The difficulty was, and is, to discover in such patients the focus of infection, or its sequels, which might be the cause of the psychosis.

We are not entitled to make a diagnosis of "neurosis" until we are completely satisfied that, as far as our means of investigation permit, no organic disease is present. When we remember that, in respect of the abdominal viscera, though there is little more to learn of their structural diseases, there is little yet learnt of their functional disorders, we may still be merciful and reluctant in our use of the word "neurosis." The physiologists, owing to their concern with mice rather than with men, have not kept pace with the surgeon in his advancing knowledge of the normal and disordered function of the abdominal viscera. Though an organ may appear to the naked eye to be normal in position and in structure, we cannot be sure that its functions are unimpaired, or that its relations with other organs have suffered no change. When the physiologist works as long in the wards and in the operation theatres as in the laboratory, we may hope to fill up some of the many considerable gaps in our knowledge of functional anatomy.

Each generation of students in medicine, as in other sciences, has to make its own experience. Positive knowledge we may derive from the store erected by our intellectual ancestors, but the application of this knowledge, the proof of it, lies with ourselves. In our purposeful testing of truth we are prone to error. Experience is the name we give to our mistakes. After I had learnt by experience of this plain association of disordered mental conditions, of "functional psychoses," with visceral disease I discovered that a century ago the same view had been held and taught by Abernethy in this country and by Pinel in France. Chalmers Watson, himself a pioneer in this branch of inquiry, quotes Pinel as saying in 1809

"It seems that the primitive seat of insanity generally is the region of the stomach and intestines, and it is from that centre that the disorder of intelligence propagates itself as by a species of irradiation."

That functional psychoses may be dependent upon minute changes in structure in the brain is indicated by the work of Cotton, who describes a "fatty degeneration of cortical nerve cells." In treating these patients he holds that we are dealing, not only with a disorder of the mind, but with a structural disease of brain tissue.

The experiences to which I have referred accumulated slowly. Their general effect was to make me less reluctant to consider surgical treatment for obvious organic disease in those suffering from grave forms of mental disorder. About fifteen years ago I was consulted by a medical man who in childhood had suffered many times from appendicitis, and in adult life had been attacked by hepatic colic, lately accompanied by jaundice, rigors, and wasting. It was clear that there was an obstruction of the common bile duct by a stone, and that there was a degree of chronic pancreatitis,

and that these were possibly linked up with the course of the appendix which had affected him in early life. But the doctor was "nervous", his form of insanity was of the kind now described as "manic depressive." The effect of a major abdominal operation upon a man with a grave mental disorder had to be considered. I have a useful ready rule, that "it is unwise to allow a patient to suffer or to die from one disease remediable by surgery because he happens to have another." The patient accepted operation, made the usual recovery, and in his own words, a "cloud was lifted from his brain." He has been at work, except for holidays a little longer than I feel able to take, ever since, and has had no breakdown in mental health. In all I have operated upon four cases of this form of insanity, and in three the improvement in mental health has been considerable. The fourth was certainly not improved, and though there are longer intervals of apparent normality the "attacks" are as grave as ever. A good deal depends, no doubt, upon the stage at which such patients are seen. The surgeon has very properly been reluctant to undertake any surgical adventure if there are grave adverse circumstances. He has not always realized that such circumstances may perhaps afford more compelling reasons than any for early surgical relief. Nor that it appears probable that certain mental disorders are directly dependent upon distant organic diseases, often infective in origin, the removal of those likely causes must be undertaken without misgiving.

In the case of a distinguished medical man upon whom I operated for chronic appendicitis and gastric ulcer, out-breaks of mental disorder had necessitated his admission for two long periods. At the time I was consulted about him grave questions were raised as to his mental state and as to the effect of the order of an operation upon him. He contemplated operation with almost a frenzy of fear and horror. My opinion that operation should be delayed only until the advanced dental infection was removed seemed enlightened to have disastrous consequences upon the patient and to be a source of deep anxiety to his relatives. All ended happily, however. The usual routine of my abdominal cases was followed, the oral sepsis was first eradicated (this, I insist, must be done, and any other infection treated), the diseased appendix was removed, and partial gastrectomy was performed. Since the operation, now a few years ago, there has been unimpaired mental clarity and strength.

It is interesting to observe that a few of the "insane" patients upon whom I have operated have been members of my own profession. All the attributes of mind and character embraced in the word "sanity" should find a high expression in the doctor. The results of operations upon which mental no less than physical health depends are submitted to a sterner test than usual. The after-history of my cases bears eloquent witness to the value of Hunter's work.

That focal infections, with the organic diseases which they may originate, are capable of causing serious mental disturbance is, I suppose, no longer a matter of doubt. But certain aspects of the problem require careful investigation. We wish to know the frequency of "septic psychosis," of mental disorder due solely to septic infection. We seek to discover the degree of contributory influence exerted by sepsis upon mental aberrations which are primarily psychogenic. What influence has focal infection upon those whose heredity involves them in neuropathic or psychopathic tendencies, or upon those suffering through stormy crises of adolescence, or passing tranquilly through the lethargic involutions of senescence, or upon those who suffer the physiological excitement of child-bearing and lactation? In all these infections, no doubt, find a few victims. We desire to learn also something of the peculiar circumstances in which a very prevalent disorder, or sepsis, is sometimes able to exert the gravest influence, and at other times seems inert even though present in an advanced stage. In this the whole question of immunity is engaged.

Focal infection is certainly free to cause the most serious effects at a distance, while arousing no suspicion of its existence. The distant and apparently unconnected

may make progress, and prove fatal without a sign of local disturbance. This cryptic quality is the source not only of danger but of disbelief. It seems at first hearing quite incredible that results so grave and so formidable could be the direct consequences of causes so trivial and remote. But that they are is now beyond the region of dispute.

The organisms responsible in the occult infections are almost always streptococci. Numbers of them are described, and to the variants descriptive titles are given. The cultural characteristics as tested in the laboratory are classified. Some day it will be generally recognized that the human body, variously constituted, is a fertile culture medium, and that organisms may also be classified according to their choice of a specific human soil in which to grow. Rosenow speaks of the elective localization of micro-organisms, and this may be decided by qualities of soil no less than of germs.

So far as my own work is concerned the infective agencies which appear to be sometimes associated with mental disease are in the teeth, the facial sinuses, the alimentary tract, and the gall bladder. We know, I think, that these infections are often connected with one another, that oral sepsis may, and often does, precede organic disease in the stomach, that infections of the appendix lead to diseases of the gall bladder and pancreas, and that infections, wherever arising, are apt when they reach the caecum and ascending colon to remain there, long after the primary focus has ceased to be active. It would appear that among the many causative agencies producing diseases of the mind, infection may assuredly be counted as one. Other factors are obviously at work also, and by comparison with them infection may take a subordinate place. My work shows at least this—that mental instability and "insanity" may sometimes be relieved, and apparently permanently removed, by eradication of a focus of infection, or removal of the diseases it has originated. I have seen more than enough to convince me that the doctrines of Lister applied, not only to surgery, but as by William Hunter to general medicine, may find a very fruitful application in the investigation and treatment of cases of mental disease. The work of Cotton and Draper in New York, of Hall in Vancouver, and of Graves in this country seems to set us a new standard of inquiry in this branch of medicine, and to show that no mental hospital will in future be considered as adequately equipped unless it has an x-ray laboratory, a skilled bacteriologist, and can command the services of an enlightened surgeon.

#### DISCUSSION

Dr CHALMERS WATSON (Edinburgh) said that the view that a septic focus in the teeth, sinuses, tonsils, prostate gland, or gastro-intestinal tract might be the cause of common remote systemic disorders was gradually gaining ground, and the work of Rosenow was of great value in helping to explain the mechanism of its production. For many years the speaker had taught that diseases of the nervous system, such as disseminated sclerosis and many acute and chronic mental diseases, took origin in a septic focus in the gastro-intestinal tract, including the gall bladder, or elsewhere this being most frequently a secondary development from sepsis in the mouth. In this connexion it was a further hopeful sign that attention was now commencing to be given to the important subject of the cleansing of the colon. More attention should be directed to the examination of the stools and urine as a guide to the diagnosis and treatment of many general and mental disorders. The use of the senses of sight and smell in the case of the stools, after the repeated use of a Plombières douche, was the main essential, this examination should be combined with a careful naked eye and microscopic examination of the urine for the presence of bacteria and cells. Healthiness of the mouth, bowel, and urine must be secured, and some standards ought to be established. The excessively putrefactive condition of the stools which was apparently accepted as normal to-day could be proved to be abnormal, it indicated a profound

disturbance in the balance that normally obtained between the bacteria in the bowel and their host. Restoration of the normal balance, quantitatively, was of great value in treatment, in proportion to the stage in the disorder at which it was applied. The surgical removal of a localized septic focus, dietetic measures, directed to improve the condition of the intestinal flora, lavage of the colon, if thorough and combined with vaccine therapy, deserved more attention. According to Dr Ford Anderson, the one medicinal remedy on which Lord Lister placed his reliance was Lysol salt. To lay stress on the importance of sepsis as a cause of mental and other disorders was not to minimize the part played by such an important factor as heredity, and by disturbed conditions of nutrition, such as calcium or iodine deficiency.

Dr H. A. COTTON (Trenton, New Jersey, U.S.A.) said that nearly every mental case was physically ill at the time of admission to hospital. The work at Birmingham under Dr Crace, went beyond anything that had been done in the United States. Dr Cotton considered non-specific protein therapy in advance on the use of vaccines. He no longer recommended colectomy, but used copious colonic douches, instead. The results of this irrigation in 600 cases had been very satisfactory.

Dr T. C. GRAVES (Birmingham) began with a tribute to Dr Lewis Bruce, who had extensively discussed this subject twenty-one years ago. Dr Bruce believed that the cause lay deeper than a toxæmia, being the result of a failure to form antibodies. Dr Graves then described a case to illustrate the possibilities of thorough disinfection.

The patient was a single woman aged 21 the fifth and youngest child of a mother aged 41. The mother had had three nervous breakdowns, but was not certified and was now a mental and physical invalid. Two brothers and one sister had suffered from chronic nasal disease. The patient had had chronic otitis media since the age of 5. She was a quiet reserved girl never on the alert. Menstruation was irregular until a mastoidectomy was performed when she was 19 when it became regular. After the operation she became depressed with persecution and suicidal obsessions, she improved for a time and then grew more restless, exalted, hallucinated and confused with kataplexy manifestations. The face was covered by a scattered staphylococcal eruption, the tonsils were septic, there was pus in the right nostril, the left antrum was darker than the right and there was a mucopurulent cervical discharge. The serum was negative to typhoid paratyphoid A and B, *B. aertrycke* to Shiga bacillus, and to Flexner's Y bacillus but agglutinated Gaertner's bacillus. Eight intravenous injections of T.A.B. vaccine were followed by a rise in the titre of the serum to all the above except paratyphoid B and by considerable clinical improvement, although she remained depressed. A sinus examination then showed pus in the left sphenoidal sinus and both antra. The antra were washed out and this was followed by an exacerbation of the skin eruption. A second wash-out was followed by much improvement in the later. The brain membrane permeability value returned to normal. Another course of non-specific protein therapy was then given and ultra violet light treatment was instituted. Intranasal drainage of both antra was performed. The patient was now well and was reported to be alert as never before.

Dr Graves suggested a "septic heredity" in this case, or alternatively transmissible familial infection. The high agglutination to the bacilli of food poisoning suggested that she had acquired a food poisoning infection with neurotoxic possibilities at some time.

Dr D. K. HENDERSON (Glasgow) challenged some of Dr Hunter's statements. The Royal Medico-Psychological Association had frequently considered this topic and in 1902 the late Sir Thomas Clouston had opened a discussion on it, expressing views which were still held to-day. It was not true that no attention had been paid to the possible influence of sepsis as a cause of mental disorder previous to the publication of Cotton's reports. The work of Kopeloff, Kirby, and Chenev had been much better controlled than was that of Cotton, and accorded more with the opinion of psychiatrists generally. Kopeloff and Kirby had examined 120 patients divided into two groups as nearly identical as possible. One group was treated surgically, while the other group had no surgical treatment. The percentage recovery rate of the manic-depressive patients in the two groups was equal, while patients with dementia præcox showed a slightly lower recovery rate in those operated upon than in those left alone. Dr Hunter

had generalized from one case. It was a commonplace in psychiatry to say that each case was an individual problem, but instead of accepting this Dr Hunter said, "Here is one case, see the brilliant result accomplished, there must be hundreds like it." Take the case which Dr Hunter had quoted with so much enthusiasm and commendation. Not only was it imperfectly described, but it was diagnosed as "a septic psychosis." In the speaker's opinion the case would be more accurately described as one of agitated depression occurring at the involutional period, and if it had been properly recognized it first the patient would never have been sent to the chronic ward. The course of the illness was quite in accord with psychiatric experience, and the increased attention, the change to better surroundings, and the building up of resistance had as much to do with recovery as the removal of her teeth. To say that the failure to remove the teeth in the first instance caused the patient's detention in hospital for two years was an unwarrantable assumption. Similarly in Dr Hunter's second case, with its acute onset, tempestuous course, and recovery with good insight, a good prognosis would have been given, and the operative procedures were merely concomitant. Dr Hunter had attempted to coin a new psychiatric term, for many years psychoses with toxins and infections had been recognized, and such a term as "septic psychosis" was not required. To divide all psychoses into the septic and the others was not permissible on the actual facts. It was very dangerous to state that because something existed in a given mental case that something was the specific agent. If in some half a dozen cases there was a *B. coli* or streptococcal infection which had not given rise to clinical symptoms pointing to a toxic involvement, such a factor was merely incidental, and might or might not have any influence on the course of the psychosis. Dr Hunter had given no clinical picture of the disease which he had named "septic psychosis." It was important to investigate all the facts carefully in every case, and not to jump to conclusions. Many a healthy abdomen had been mutilated, and many a serviceable tooth removed as the result of ill-grounded theories of the etiology of mental illness.

Dr W F Mearns (Cheddleton) agreed with Dr Henderson, and said that the evidences of chronic sepsis were no more frequent in the insane than in the sane. Sepsis was as a rule a secondary cause of mental disorder. The hypothesis that sepsis was an important cause of mental illness was not new, forty years ago colonic lavage and Bouehrid's mixture of naphthalene, chloroform, and glycerin were popular in the asylums. As long ago as 1902 he had asked a surgeon to perform a short-circuiting operation in a patient with dementia praecox. The recovery had not been materially raised by antiseptic measures. Antigenous vaccines were disappointing. The results of serological, metabolic, and endocrinological tests had all given results that were not at all specific. Dr Mearns thought that the difficulty in the study of mental disorder was that the observations were made upon complex states such as paranoia and dementia praecox instead of being made upon the basal emotional feeling tones. He referred to the association of Parkinsonism rigidity with euphoria in various basal lesions, in the later stages of epidemic encephalitic Parkinsonism euphoria was almost universal. Pathological euphoria was an expression of the irritation produced in the neurones by a free flow of toxin-laden blood. In toxic mental conditions there was increased stimulation of the sphincter reflex arcs by some toxin, probably of bacterial origin, together with irritation of the basal and cortical neurones from toxins in the blood. In the absence of rupture between the basal and cortical groups, dysphoria occurred. If there were partial dissociation, euphoria was produced. It was a pity that surgeons and physicians rarely described the mental attitude and feeling tone of their cases.

Mr F Watson-Williams (Bristol) supported the view that chronic toxemia could produce a definite psychosis, just as it constantly caused a psychosis. He instanced cases under his own observation which had been relieved by operation.

Dr W A Potts (Birmingham) discerned a very distinct clinical picture in Dr Hunter's description of the term "septic psychosis" was the most satisfactory one he knew. Although chronic sepsis was as common in the sane as in the insane, the reason why it was to be considered as a cause of mental disorder was that in the insane there were many other contributing factors, while the septic infection had begun earlier and had, therefore, lasted longer and produced greater effects. Infection should always be eradicated before its serious sequels had developed. It was likewise necessary to deal with the psychological factor early, before the sepsis of later date had produced such mental disability that psychological treatment was out of the question.

Dr Hunter, in reply, insisted that the important part was the focalization of the infection. The advantage of the term "septic psychosis" was that it called attention to the cause. Kopeloff's patients were not satisfactory clinical material, the morbid process in them had lasted a long time, and the sole step taken was the elimination of a few teeth. The only patient who did well had had thirty teeth removed.

## ACUTE INTESTINAL OBSTRUCTION IN INFANCY AND CHILDHOOD.

### CONGENITAL ABNORMALITIES ACQUIRED CAUSES TREATMENT

BY

ALEXANDER MACLENNAN, M.B., CH.M., F.R.C.S.,  
Surgeon, Royal Hospital for Sick Children, Glasgow

Acute intestinal obstruction in children presents much the same symptomatology as in adults. It is a fatal malady, but with relief in prospect the prognosis in children may be somewhat less serious than in those of maturer years. As an offset to this relative benignity must be placed the fact that in many of the obstructions due to congenital malformations relief is not possible.

Children stand intestinal obstruction comparatively well, for the reason that the child's intestine is less prone to ileus than the adult's. For example, children suffer less from post-operative colic than grown-ups, and they seldom show any deterioration from minor degrees of chronic obstruction. In the main, however, the disease is able at all ages, and it does not really add any special complication to consider the matter as it presents itself in the young. There is one class of obstruction which is entitled to separate consideration—I refer to obstruction due to congenital deformities.

#### 1 Duodenal Stenosis

From time to time instances of this type are reported in the journals. Probably a complete stenosis is commoner than one which is incomplete. A feature of these conditions, as indeed of all developmental obstructions, is the tendency for the bowel distal to the obstruction to be in a state of what might be described as embryonic spasticity. Thus a functional atresia is superimposed upon the anatomical. It is to the former condition that we must ascribe the well-nigh hopeless prognosis. The obstruction in the duodenum is usually proximal to the entrance of the bile duct, it may, however, be in the region of the ampulla, while there may be anomalies of the pancreatic duct. Three varieties may be recognized: (a) those which present a gap in the continuity of the bowel and where the duodenum above is much distended, (b) those which show merely a partition in the bowel and (c) cases where the lumen is narrowed to a serious extent, this type may be due to an inherent lesion of the duodenum itself, or be the result of fibrous bands crossing the bowel, or be due to tortuous errors during development. Fortunately the condition is one of considerable rarity.

\* A paper read in opening a discussion in the Section of Diseases of Children at the Annual Meeting of the British Medical Association, Edinburgh, 1927.

for it is seldom diagnosed early enough for successful treatment. Indeed, it is rarely possible that any treatment could be curative, on account of the non-distensibility of the jejunum being almost if not always an accompaniment.

The symptoms upon which most reliance must be placed are early and persisting vomiting with in many cases, icterus. The combination of icterus with vomiting is suggestive but on the other hand there is no special characteristic about the jaundice to distinguish it from the common fleeting icterus neonatorum. As a rule these infants are brought under expert observation only after the fourth day, when intervention, even if theoretically possible is useless. The examination of the meconium may reveal that it does not contain any down from the foetal skin but a negative finding is inconclusive.

The operative repair of such a condition is one which will tax both the child and the surgeon. Gastro-enterotomy and duodeno-jejunostomy are operations having a high mortality in infants even before they show signs of breaking up but in a moribund infant there is little hope of success. The operation is practically doomed to failure if it consumes more than twenty minutes. I cannot claim a single success even though, in one instance, a gastro-enterostomy was carried out in eleven minutes the deeply jaundiced infant was 5 days old and showed a complete stenosis of the duodenum which was dilated while the jejunum was hopelessly shrunken.

### 2 Jejunal and Ileal Atresias

These conditions may be due to gaps existing in the bowel to obstructions from congenital tumours which more or less replace the gut and to impermeability of the bowel in short or long sections. The proximal bowel is usually much distended and shows a great contrast to the underdevelopment of the lumen distal to the defect. Certain of these cases are associated with errors in rotation, and the obstructions may be multiple. There is no special situation where these deformities are more likely to occur but as a rule they should be looked for high up in the jejunum or low down in the ileum in the neighbourhood of Meckel's diverticulum. Theoretically these anomalies should be easily remedied, but the underdevelopment of the lumen of the bowel distal to the obstruction forms an insuperable barrier to restoration. An enterotomy of the distended bowel is essential as otherwise the developing ileus is bound to be progressive. The proximal bowel, already encumbered by overinflation, cannot blow out the semi-solid distal intestine.

### 3 Colic Obstructions

It is said that gaps are found less commonly in the colon than in the small intestine. If we omit the pelvic colon this statement is probably correct. It is however, comparatively common to find the colon end abruptly at the place where it should join up with the rectum, but probably the commonest type is the nondevelopment of the lumen. The entire colon is apt to be involved. The rectum may be normal but in its upper part it will be found to become conical. These cases are occasionally diagnosed as imperforate conditions of the rectum. Their treatment is quite beyond the range of surgery. In cases where union between pelvic colon and rectum has failed to become established an attempt is often made to tunnel through the intervening tissue but if an entrance is gained to the lower end of the blind pelvic colon an inveterate stricture subsequently develops. A primary inguinal colotomy is the only possible solution of the trouble.

In my experience errors in rotation of the colon do not produce obstructions of the colon but rather of the ileum.

### 4 Rectal Obstructions

Malformations of the rectum are so frequently associated with malformations of the urethra and bladder that the cases are very complicated but it is the possibility of the membranous urethra being involved is remembered our treatment may be more successful. Where the sphincter is defective an artificial anus should never be made in the perineum this is the worst possible site for such an opening. As an emergency measure the sinus into a cloaca may

be widened at the expense of the perineum, but in doing so the possibility of damaging the sphincter should not be forgotten.

### 5 Fromphalos

Hernias into the umbilical cord are a class by themselves and strangulation is unusual as rupture of the covering membrane occurs too early, with the production of a fatal peritonitis. An obstruction may, however, be present, and it may involve both large and small bowel. Suffice it to say that all cases of omphalos should be operated upon as soon as possible. In one case the radical operation was successfully performed and the infant returned to bed aged 1 hour.

### 6 Meckel's Diverticulum

A more prolific cause of trouble from congenital abnormality is produced by a Meckel's diverticulum. The diverticulum may be adherent at its tip to the inner aspect of the umbilicus and a loop or loops of bowel may become entangled round this intra-abdominal pillar. The tip of the diverticulum may become adherent to visceral or parietal peritoneum, and may act as a band strangling one or more loops of bowel.

### 7 Strangulated Hernia

Among the innumerable instances of hernia it is fortunately unusual for many to strangle, yet the condition is quite common none the less, it calls for no further comment.

### Acquired Causes

It would be futile to go into all the various causes of acute obstruction in children, but I might refer to one or two types which are frequently met with. To begin with, it must not be forgotten that the term "acute obstruction" which refers to symptoms, is not synonymous with "complete obstruction" hence the dividing line between acute and chronic obstruction is a broad one. We have acute exacerbations superimposing themselves on the chronic and as in children the chronic part is masked we will have clinically, only the attacks of acute obstruction recognizable. Under this aspect of the case would come to be considered those obstructions which resulted from a tuberculous infection of the mesenteric glands with band formation or adhesions with more or less linking of the bowel (and consequent narrowing of the lumen) from a contracting cicatrix. These conditions are often associated with a healed tuberculosis, but they may crop up during the infective stage of a plastic peritonitis. How far the final stage in many peritonitis is due to obstruction is a point on which discussion might profitably take place. Whatever the cause of the obstruction the symptoms will vary according to the level and degree of completeness of the stenosis and to the degree of interference with the circulation. Symptoms indistinguishable from those produced by obstruction may be set up by other conditions without implication of the lumen of the bowel at all. For instance, strangulated omentum a strangulated Richter's hernia and a mesenteric embolism will produce a set of symptoms almost incapable of differentiation from a true obstruction. So much is this the case that we are greatly given to label a particular lesion as an example of the acute abdomen and are content if we decide for or against exploration.

It is the general custom to classify intussusception among the obstructions, and I would like to enter a protest against such an arrangement as conducing to delay in operation. Intussusception is no more an obstruction than appendicitis is a general peritonitis. Both are alike in this respect that under such a view they demand treatment before they come into their proper categories, intussusception must be operated upon before it is obstructive, as must an inflamed appendix before it gives rise to a general peritonitis. The risk of leaving an appendicitis till perforative peritonitis has developed is not nearly so serious as leaving an intussusception till obstructive symptoms set in. In intussusception which is possibly often one phase of the status lymphaticus death is apt to be sudden and entirely unexpected.

The reference to appendicitis brings to mind the

obstruction which complicates the operation. It develops about the fifth day, usually suddenly, and it requires prompt treatment. I do not refer to the ileus developing with a spreading peritonitis, but to a local obstruction of the lumen of a section of bowel.

Simple tumours rarely occasion an intestinal obstruction. Malignant tumours are so seldom found that we hardly ever think of including them in the discussion of a differential diagnosis.

The symptoms which result from the interruption of the intestinal flow may be briefly considered.

1 *Vomiting*—At first this may be a reflex phenomenon, it soon, however, becomes a sign of reversal in the direction of the intestinal current. It is persistent, and its character changes in the well recognized manner so that it becomes pathognomonic.

2 *Visible Peristalsis*—This symptom is probably more fully developed in the chronic obstructions, but it is an important aid to diagnosis even in the acute. It may be accentuated by tapping the abdomen and in some cases by lightly scratching the skin.

3 *Distension*—To begin with, this is the alternative to spasm, but it soon becomes permanent to the exclusion of the spasm. When the entire small bowel becomes distended the well recognized designation of "ladder abdomen" to the appearance shown is a condition of sinister meaning. No doubt the distension is due to the evolution of gas which cannot find an exit, but soon the overdistension passes into a paralysis, so that mere escape of the gas brings no relief.

#### *Symptoms Due to Interference with Function*

These might be referred to under the following sections.

(a) *Toxaemia*—Chemical changes in the contents of the intestine soon take place, the initial disturbance cannot be explained in this way, but later symptoms and the tendency to death are certainly due to this cause. The experimental work done to elucidate the results of obstruction of the intestine is considerable, and while it has been enlightening it has added an element of complexity. The action of the chlorides, which are so quickly reduced in the circulation, has been proved to be of the greatest importance in such toxæmias as we are considering, but that their repletion is the desideratum is not yet established. Whether a distortion of metabolism takes place in the wall of the bowel, due to the pressure of the distension or to chemical changes instituted by the infection of the entire fluids, is not decided. It is, I think, proved that the gas-producing organisms make highly toxic substances, and we thus have to attempt to inhibit such manufacture from the point of view of gas as well as toxin. It is more than likely that a vicious circle is set up—the more toxin the greater the inflation, and vice versa. Distension alone is serious from its pressure effects on the thoracic organs, its interference with deep respiration, and with the heart. From clinical experience, as from scientific research, the emptying of the bowel, etc., is essential.

(b) *Disturbance through the Sympathetic*—Some of the symptoms might be so explained. By warring out the action of the sympathetic ganglia the pneumogastric inhibition becomes more active or the vagus is initially stimulated, and the heart shows the effect sometimes very rapidly. Thus irregularity of the pulse in intussusception is often an early sign. Of course, a toxin might well have a direct action on the heart without reference to the nervous system.

(c) *Paralysis of the Bowel*—This condition will develop at a period governed to some extent by the nature and situation of the obstruction, and whether the obstruction be complicated with peritonitis.

(d) The changes in the circulation of the bowel and the reflex stimuli will account for the effusion of fluid which takes place almost invariably with an obstruction.

(e) *Peritonitis from Perforation*—Is the result of gangrene this very serious catastrophe may set going its own series of symptoms, but as a rule death takes place before this occurs. Examination by x rays is rarely possible, as we rightly hesitate to allow the expenditure

of the time required, to say nothing of the difficulty and disturbance caused by trying to force the retention of the opaque meal.

#### *Treatment*

The stomach should be washed out early in the anæsthetic period, and great care should be exercised that none of the stomach contents finds its way into the tract. I do not propose to touch on all the various plans or treatment possible of adoption, either from the point of view of operation or as adjunct treatment, but rather to refer to some aspects of the matter which are discussible.

After opening the abdomen, distended bowel should be avoided, and a gentle search for undistended gut instituted, the obstruction being approached from the sound end. After the obstruction has been relieved, if anything further is required we are often placed in a dilemma whether to resect, perform a lateral anastomosis, or to be content with an enterotomy. There does not seem to me to be any great reason why an enterotomy should not be done irrespective of whatever else may have been demanded. We dislike making a fistula, but these fistulae (in children at any rate), if made through the omentum, show a great tendency to spontaneous closure. The omentum should not be pushed aside, but the most prominent loop of bowel above the umbilicus should be drawn through a hole made in it. An enterotomy likely to function should be made high in the jejunum.

The handling required in resecting is against its success, and so the quick methods of performing intestinal union are attractive. The possibility of adding infection to the already damaged abdominal contents is to be avoided at all costs. It is a decided advantage to leave as much saline in the abdomen as it will hold, and I think the addition to it of 5 per cent. cane sugar, a half to one cubic centimetre of pituitin, and the same quantity of adrenalin, is beneficial.

*The Anaesthetic*—The choice of an anaesthetic is of importance. Most surgeons dislike chloroform for an intestinal obstruction, but when chloroform gains in its greater power of producing muscular relaxation. A shorter incision suffices, and manipulation in the abdomen is facilitated, with consequent shortening of the operation time. As obstruction is more often associated with an alkalosis than an acidosis, it is possible that this general dislike of chloroform may not be an entirely sound doctrine. In this connexion the recent proposal to introduce pepsin and hydrochloric acid with saline into the peritoneum as a remedy in peritonitis may find support, and the almost invariable rule to give alkalis and glucose may require to be sometimes departed from. The advice to give excess sodium chloride may well receive a careful trial, not only because its quantity has been reduced, but also because it has a direct antagonistic action on the toxins developing in the distended bowel. It certainly tends to reduce the dehydrating effects of the poisons.

*Enteritis after Operation*—This is a condition which is prone to develop in children at all times, and more especially after damage to the intestine. Grey powder and so-called intestinal antiseptics may be indicated. I have found the oral administration of normal horse serum to be most effective.

*Pneumonia*—Tactical changes in the atmosphere, in the temperature of the sick-room, etc., cannot account for the onset of this complication, but it is almost certainly due to a toxæmia or septiciæmia.

*Pyelitis*—After intestinal operations I think there is a direct tendency for a *Bacillus coli* septiciæmia to become established, and I have observed a few cases where pyelitis resulted from an enterectomy. The urinary infection has thus a common source with that causing pneumonia.

There are many other complications which occur, such as those referable to thrombosis, etc., but it is unnecessary to elaborate the matter further.

#### *Prognosis*

The important item in the prognosis is the degree of ileus present, and this will depend to some extent on the amount of handling which has been found necessary at the operation, as well as upon the nature of the obstruction.

and the general robustness of the child. Where craniotomy has been performed the prognosis is bad. Scientific investigation may help us to neutralize the toxins and restore motility to the overstretched intestine.

An early diagnosis, followed by prompt intervention, is still the thing which matters most.

# DISCUSSION

Mr L. E. BARRINGTON-WARD (London) emphasized the points in symptomatology and physical examination which his experience led him to believe were most helpful in diagnosis. He hoped the day was not far distant when, as a result of earlier diagnosis, the surgeon would seldom be faced with the difficult and debatable problems of how to deal with an irreducible mass in intussusception or treat a length of gangrenous intestine. The patient's age was often of assistance in deciding beforehand the nature of an obstruction in early life. He referred at length to some of the rarer forms of intestinal obstruction in childhood: (1) Internal hernia—(a) through a congenital hole in the mesentery or omentum, (b) diaphragmatic, (c) retroperitoneal. (2) Volvulus of the small intestine apart from volvulus neonatorum. He based his remarks on the latter form upon a series of six cases which had occurred during a period of twenty-five years at Great Ormond Street Hospital. All were dependent on a deficient attachment of the mesenteries of the small intestine and ascending colon. The diagnosis of the condition from ketonuria had presented great difficulties, and he thought the character and time of onset of the abdominal pain were the points which were likely to be of most help in differentiation. In the treatment of intussusception he had tried and been impressed with the value of Farris' method which consisted of an injection of air into the colon followed by a small abdominal incision to enable the reduction to be completed. This procedure eliminated the element of uncertainty of the older method of reduction by inflation alone and was associated with less shock than complete reduction by laparotomy. Where reduction was impossible he was in the habit of resecting and performing an anastomosis at once. The infant did not seem to tolerate temporary drainage well.

Mrs. GEORGE HERZFELD (Edinburgh) referred to the fact that in acute obstruction in children abdominal distension was usually not a striking feature. She emphasized the desirability of combating dehydration and washing out the stomach as preliminary measures. As a routine anesthetic in these cases she preferred open ether combined with local infiltration but recently had been using spinal anaesthesia successfully in cases of intussusception. Where distension of the bowel was marked she did not hesitate to perform immediate puncture of the gut by means of a fine trocar and cannula. She did not agree with Mr. MacLennan's contention that obstructive symptoms were so definitely secondary in intussusception that to include the latter under the category of acute obstruction was calculated to lead to delay in operating. It was her experience that in the majority of cases obstruction of the bowel was complete within three or four hours. She had had 109 primary cases of intussusception under her care during a period of seven and a half years—71 in male and 38 in female children. 18 were in children under 1 year old. One child was moribund on admission and died without an operation. Spontaneous reduction occurred in three instances. Immediate operation was performed in the remaining 105 cases. A recurrence took place in 7 and in one case proved fatal. Including the recurrence 112 operations were carried out with 24 deaths giving a death rate of 21.4 per cent. In the last 50 cases, however, there had been only 7 deaths—that is a mortality of 14 per cent. This improvement was chiefly due to earlier diagnosis on the part of the practitioner. As regards the type, 84 per cent occurred in the ileo-caecal region, 11 per cent were of the colic and 5 per cent of the enteric variety. All the colic cases recovered. Most of the 7 recurrences took place from eight to fifteen months after the primary operations. It was interesting to note that in 2 of the recurrent cases fixation of the caecum had been performed at the first operation. There were 9 cases

in which resection was found to be necessary, with 5 deaths. Tearing of the peritoneum even when extensive was not in itself regarded as an indication for resection. During the same period 16 cases of obstruction due to abdominal tuberculosis had occurred; there were 6 deaths, all in children under 3 years. Of obstruction due to irreducible and strangulated hernia, there were 22 examples, the average age was 5½ months. Resection was necessary on two occasions once in a baby of 12 days. All the patients in this group recovered. In the course of 197 cases of acute appendicitis 6 examples of true post-operative obstruction arose. The average time at which operation for this complication was called for was the fourteenth day after appendicectomy. The methods of dealing with this emergency were discussed. The only fatal case was one of streptococcal appendicitis in which obstruction occurred on the fifth day after operation and an enterotomy was performed.

Mr. T. C. PEARCE (Newcastle-on-Tyne) dealt with the sequence of development and relative importance of the symptoms and signs of obstruction. He maintained that it was often possible to determine beforehand the nature of an obstruction from a carefully taken and interpreted history. He quoted cases illustrative of the difficulties of diagnosis with special reference to ketonuria and Henoch's purpura. Chloroform as an anesthetic was to be avoided.

Mr. NORMAN M. DODD (Edinburgh) submitted two cases for consideration: (1) that inasmuch as children suffering from acute intestinal obstruction to varied operations up to one hour's duration remarkably well, delicate accurate technique should not be subordinated to mere speed in operating; (2) that resection was possible the best treatment in certain cases of intussusception in which the bowel though reducible and viable was yet severely injured in the process of reduction. He developed his argument from a review of 20 cases of intussusception which he had been called upon to treat during the past two years. All these cases had been operated on and 4 deaths had occurred. In 3 of the fatal cases the condition was so severe and advanced on admission that a fatal issue was almost inevitable, he had thought it right however to give them the chance offered by operation. The fourth fatal case was in a baby of 5 months who had a double intussusception of fourteen hours' duration. Reduction was extremely difficult but was finally accomplished with viable bowel. The immediate effect of the operation was negligible but the child's condition rapidly deteriorated and death took place after twenty hours. The cause of death in Mr. Dodd's opinion was toxic absorption from an excessively bruised bowel, and he believed that removal of this injured segment might have been a life-saving measure. Excluding the 3 unavoidable fatalities his series was reduced to 17 with one death. The 15 recoveries took place in cases which on the average were of a severe type. In operating great speed had not been aimed at. It was his rule to make a "gridiron" or rectus displacement incision to carry out fixation by the fine interrupted silk sutures and to close the wound deliberately in layers. Further 3 of the 17 patients were subjected to procedures of considerable magnitude. One was a baby of 10 months who had an ileo-colic intussusception of forty-three hours' duration. A good recovery followed an operation which occupied thirty minutes. Four days later an enteric intussusception developed necessitating a second laparotomy. Another child of 4 months had an ileo-caecal intussusception of five days' duration. Reduction was impossible and a right hemicolectomy with lateral anastomosis by the aseptic method was performed. The operation lasted one hour. The third was a child of 3 months with a gangrenous ileo-colic intussusception of three days' duration. A right hemicolectomy with end-to-end anastomosis by the aseptic method was carried out. Recovery in these three cases was uneventful.

Dr. H. C. CAMERON (London) spoke of the need for early diagnosis when confronted with the grave symptoms of intestinal obstruction in a newborn infant. There was too great a tendency to wrap the child in a shawl and adopt

a fatalistic attitude. In duodenal obstruction the diagnosis could only be made by an x-ray examination in the first few days of life. One such case of duodenal atresia operated on by Mr. Stewart made a complete recovery. With regard to acute intussusception, he called attention to the contrast in practice prevailing in Scandinavia. There, in 80 per cent of the cases, taxis through the abdominal wall without laparotomy was successful. Secondary laparotomy was necessary in the remaining 20 per cent. He referred to the case of a small boy suffering from extreme ketonaemia, with the characteristic tenderness of the abdominal muscles, who had developed after some days of illness a complicating intussusception. Mr. Jennings Marshall had reduced the intussusception in a moment, and without difficulty. In this case it was the ketonaemic amyotonia that explained the ease of reduction. The differential diagnosis of intussusception from follicular colitis and Henoch's purpura was helped by noting the odour of the blood-stained evacuation. In intussusception the motion was odourless, in the other conditions foul-smelling. Lastly, he spoke of the immense value of a blood transfusion before a young feeble infant was submitted to a severe operation.

Dr. C. P. LAPAGE (Manchester) thought that the history in cases of intussusception was so distinctive that it was often possible to make a diagnosis before blood appeared in the stools, or even on the finger after rectal examination. The earlier spasms of abdominal pain were often overlooked unless the mother was closely questioned. In the differential diagnosis between obstruction and ketonaemia a history of previous attacks and the presence of certain clinical peculiarities in the latter group were helpful. In Henoch's purpura the difficulty was greater, but as a rule the blood in the motions was more profuse than in intussusception, and the purpura patients were often peculiarly sensitive to rectal examination. He protested against the indiscriminate use of purgatives which was still so common in the treatment of patients with abdominal symptoms. As an illustration of the ability of the youngest infant to tolerate severe surgical procedures, he referred to the case of a baby of a few weeks who had had a mesenteric cyst of the size of its own head successfully removed by his colleague Mr. Moiley.

Dr. MARGARET TOD (Edinburgh) pointed out that it was often by no means easy to distinguish between acute enteritis and intussusception. Enteritis might determine an intussusception and the history of the antecedent enteritis confuse the issue. On the other hand, at the outset of an intussusception there might be one or two greenish motions, suggesting a diagnosis of enteritis. She had been impressed, especially during a recent visit to America, by the great value of transfusion as a pre-operative or post-operative measure.

## DEAF-MUTISM DUE TO A BILATERAL LESION OF THE AUDITORY SENSORY AREAS

BY

J. S. FRASER, M.B., F.R.C.S. ED.,  
Surgeon, Ear and Throat Department, Royal Infirmary, Edinburgh,

AND

SARAH H. NELSON, M.B., CH.B.,  
Research Scholar, Royal Infirmary, Glasgow

In the vast majority of cases of deaf-mutism the lesion is situated in the ear itself. Deaf-mutism is usually divided into the congenital and the acquired varieties.

In Switzerland endemic congenital deaf-mutism is met with in association with goitre and cretinism. Here the lesion is in the middle ear, the niches of the oval and round windows being filled with connective tissue. Many of these patients, however, have fairly good hearing, and the mutism is mainly caused by their feeble mental development. In this country sporadic congenital deaf-mutism is by no means uncommon. The lesion in these cases is in the inner ear and, as a rule, consists in maldevelopment of the membranous cochlea and sacculus—the pars superior of the

labyrinth—while the utricle and semicircular canals are normal. In such cases the vestibular apparatus is usually normally to the rotation and caloric tests, though the patient is almost or entirely deaf.

Acquired deaf-mutism is due to labyrinthitis, which may result (1) from the otitis media of such infections as scarlet fever or measles invading the inner ear, (2) from injury, as in fracture of the base of the skull involving both labyrinths, (3) from purulent infiltration of the labyrinth from the meninges—as, for example, in cases of epidemic cerebro-spinal meningitis, in which the infection may pass to both labyrinths along the eighth nerve, or (4) from congenital syphilitic infection of the inner ear, which, as a rule, only occurs after the age of 9, when the child has already learned to speak. The vestibular tests in cases of acquired deaf-mutism give negative results.

The microscopic changes in the ear in these various kinds of congenital and acquired deaf-mutism have been well known for many years from the work of Politzer, Alexander, Neumann, Denker, Mondini, Scheibe, Gray, and others. Caster, however, holds that deaf-mutism is usually due, not to lesions of the ear, but to changes in the cortical hearing area which may be caused by intermeningitis. Though we hold that such an occurrence is extremely rare it must be admitted that all cases of deaf-mutism have not been explained by histological examination of the ears. For this reason the following case appears to be worthy of publication.

A male child, aged 3, had suffered from bilateral middle ear suppuration at the age of 1 year, the cause was unknown. Three months before admission to hospital on August 2nd, 1921, an abscess formed behind the left ear and was opened by his doctor. A week before admission a swelling appeared behind the right ear, with pain and loss of sleep. There was no history of giddiness or sickness. Examination showed the ear of an old mastoid abscess behind the left ear. The left meatus contained purulent discharge and a polypus, there was also profuse discharge from discharges and a subperiosteal abscess was present. The child did not speak, but his cry was like that of a child who heard.

On August 3rd a radical mastoid operation was performed on the right ear, there was erosion of the cortex, and the antrum contained cholesteatoma. The incus was absent, there was slight erosion of the lateral canal, and granulations were present in the tympanum. A cold lotion applied to the inner wall produced prompt conjugate deviation to the left. A skin graft was applied, leaving the inner wall of the antrum and aditus uncovered over the erosion in the lateral canal, and the wound was closed. The temperature remained normal after the operation, and the wound and operation cavity were satisfactory on August 7th, seventeen days later the patient was discharged.

Nearly one year later, on June 13th, 1922, the child was brought back with an acute exacerbation of the chronic middle ear suppuration in the left ear. An abscess had been present over the left mastoid for five days, but there was no vomiting, the child still did not speak, and did not appear to hear. A radical operation was performed on the left ear, there was a subperiosteal abscess and the cortex and whole of the mastoid were hollowed out by and the cortex and whole of the mastoid of the lateral canal. The cholesteatoma. There was no erosion of the lateral canal. The ossicles were absent and the vestibular apparatus responded promptly to cold lotion. A skin graft was applied. The temperature continued normal until June 22nd, when it rose to 99°, and on the next day to 101°, there was slight stiffness of the neck and Kernig's sign was present. The operation cavity appeared satisfactory and there was no nystagmus, but a lumbar puncture showed cerebro-spinal fluid under pressure and slightly turbid. The patient had a lemon yellow colour.

On June 30th the temperature rose to 103°. At an operation on July 1st the sinus wall was found to be greyish yellow and thickened. Neumann's labyrinth operation was performed on the left side, the internal meatus was opened through the vestibule and a flow of cerebro-spinal fluid was obtained.

On the day after the operation the temperature remained between 100° and 101°, drainage through the internal meatus was not very free. On July 3rd the temperature was 102° and the pulse 164, the cerebro-spinal fluid was still draining. Two days later the temperature was 101°, and death ensued.

At two necropsy purulent meningitis was found at the base and over the left cerebral hemisphere. There was no thrombus of the venous sinuses. The infecting organism was the pneumococcus.

*Microscopic Examination of Right Ear.*—The Eustachian tube was closed by thickening of the submucosa, which showed cystic spaces. The tympanum, attic and antrum were lined with squamous epithelium, there was a gap filled with fibrous tissue in the footplate of the stapes, though the crura were entire. It showed that the gap in the footplate was not due to injury at operation. The round window membrane was only slightly thickened. The cartilage bone capsule of the labyrinth was local thickened. Two cartilage bone capsules were dilated, and some of the vessels of the footplate antrum, through the footplate, traced from the inner wall of the antrum, through the middle ear to the area of the posterior cranial fossa. On the left side this may have been a possible route of infection from the middle ear to the meninges. The vessels of the modiolus were dilated, and the membrana was slightly depressed, as is usual in cases of meningitis.

The cochlear nerve and ganglion appeared to be normal if allowance be made for the presence of meningitis. Cortic organ was degenerating (a possible *post mortem* change) but the acoustic papilla was well formed and the membrana tectoria was in the normal position. The bony spiral lamina was well filled by the nerve and the stria vascularis appeared to be normal. The spiral ganglion was infiltrated with pus cells from the internal meatus. A few pus cells were present in the scala tympani in the lower part of the basal coil near the opening of the perilymph aqueduct. There was a little curdled lymph just internal to the footplate of the stapes the neuro-epithelium of the utricle showed desquamation possibly a *post mortem* change. The sacculus appeared rather dilated and the otolith membrane was in parts separated from the neuro-epithelium. The ductus endolymphaticus was healthy. The crista and ampullae of the canal were normal except for desquamation of epithelium. The subarachnoid space of the internal meatus was crammed with pus cell. The meningitic infiltration surrounded the vestibular nerve to the utricle and superior and lateral canal, and extended along the seventh nerve almost as far as the geniculate ganglion.

Middle-ear suppuration alone even when bilateral and dating from earliest childhood does not produce such a severe degree of deafness as to give rise to mutism in a child of 4 years. The cold caloric test, carried out on the operating table had shown that on both sides the vestibular apparatus reacted promptly, and that in consequence a former labyrinthitis might almost be trunk be excluded as the cause of the deaf-mutism. Consequently one of us (J. S. F.) expected to find on the microscopic examination of the right ear the changes usually associated with sporadic congenital deafness—namely, malformation confined to the cochlear canal and sacculus. Such examination however indicated an apparently normal inner ear. It allowance is made for *post-mortem* changes and for the results of basal meningitis. The cause of the deaf-mutism therefore remained a mystery until the histological examination of the brain carried out by one

of us (S. H. N.) revealed abnormality of the auditory sensory area in the cortex on both sides.

On microscopical examination of the auditory paths and centres a basal meningitis of pneumococcal origin was seen to be present, and this confused to some extent the histological picture. A "foamy" degeneration of the nerve cells was observed throughout the brain, this was presumed to be due to the meningitis. Haemorrhages were noted in the eighth nerves, but no degeneration, as shown by Weigert's method was seen. The posterior quadrigeniculate and mesial geniculate bodies were well developed.

In the cortex the pathological process was more of a meningo-encephalitis, as perivascular infiltration was observed. The transverse gyri of Heschl (auditory sensory areas) showed marked changes. The cells of the cortex in these regions were represented by small rounded elements which were nerve cells deprived of cell body and processes. This degeneration caused the topography of the cortex to be lost. The pathological condition was present on both sides and was in marked contrast to the histological picture of the outer borders of the superior temporal gyri (auditory psychic areas) Broca's area pre-Rolandic areas, angular gyrus, and the area round the calcarine fissure, which showed normal development.

The case was one of acute pneumococcal meningitis, with the existence of a more chronic lesion in the transverse gyri of Heschl. The fact that the auditory psychic areas were developed presumed the normal development at one time of the auditory sensory regions. It is probable that the auditory sensory areas were subsequently destroyed by some disease process.

## PREVENTION OF EAR DISEASE BY REMOVAL OF TONSILS AND ADENOIDS

BY

A. J. WRIGHT, M.B. F.R.C.S.

Surgeon to the Ear, Nose and Throat Department, Bristol General Hospital

THE answer to the question to what extent the removal of the tonsils and adenoids prevents ear disease is of some importance. I have been accustomed to believe and to preach that in the very great majority of cases chronic middle-ear disease in the adult has its origin in childhood. I have also thought that infection associated with enlarged tonsils and adenoids is responsible for such disease in an over-

whelming majority of cases and that excision of these should largely prevent or arrest the middle-ear infection. The removal of tonsils and adenoids by operation has now been widely employed for at least twenty years and it occurred to me that it might be interesting to try to ascertain to what extent this proceeding was actually diminishing middle-ear deafness in the adult. For this purpose I have made a somewhat laborious statistical examination of the records of my private cases from 1910 until 1926. In this period a total of 1,077 cases of middle-ear disease were dealt with. In judging the result many factors no doubt must be taken into consideration but I believe that, taken as a whole my practice can be considered as presenting typical results. I have done no particular work in any one direction which would lead to an undue proportion of any particular type of case being referred to me.

My first step was to see to what extent I could demonstrate a variation in the incidence of middle ear disease as a whole. I was surprised to find that over this period of sixteen years, there was no sign of any diminution in the relative number of cases. As a check I worked out the average age of the cases of middle ear disease, and again found that this was practically constant. Being unwilling to believe that our efforts at prevention were entirely fruitless I analysed the figures under three separate groups—namely chronic non-suppurative, chronic suppurative, and acute suppurative middle-ear conditions.

Taking first the chronic non-suppurative cases, the curve indicating the incidence of these cases does show quite an appreciable downward tendency—that is cases do seem to

be diminishing in frequency (Chart 1). In support of this the next curve (Chart 2), giving the average age of cases shows an upward tendency, which would suggest that cases are now being chiefly drawn from the period prior to that in which tonsils and adenoids

Charts showing the incidence and average age in cases of chronic non-suppurative, chronic suppurative and acute suppurative middle-ear disease.

were removed. In the chronic suppurative group there is a less marked diminution in the incidence (Chart 3) and a less marked rise in the average age (Chart 4). Acute suppurative on the other hand shows a decided increase in the number of cases, without any obvious change in the age incidence (Chart 5). This increase in the number of cases of acute suppurative is I suggest due to the recent prevalence of influenza.

To sum up. There is a decided diminution in the incidence of cases of chronic non-suppurative middle-ear disease but this is balanced by an increase in the cases of acute suppurative due to influenza so that the gross total of cases of middle-ear disease is unaltered. Fortunately,

however, acute suppuration seldom leads to deafness. There is, therefore, a diminution in the number of cases of adult deafness, and this decrease should be progressive, owing to the increased frequency with which tonsils and adenoids are removed in childhood.

## RADIOGRAPHY IN MASTOID DISEASE \*

BY

STEPHEN YOUNG, M.B., CH.B. GLAS.,

Surgeon to the Out-patient Department for Diseases of the Throat and Ear, Glasgow Royal Infirmary

This paper is based on the study of the radiographic pictures of over 500 cases, normal and abnormal.

Before dealing with the radiographic study of the mastoid, it is necessary to consider the normal mastoid development at the various ages and the normal mastoid structure. According to Wittmack's researches, the development of the temporal bone may be divided into three periods: (1) Formation of the tympanum, epitympanic recess, and the mastoid antrum, continuing to the end of the first year. (2) Formation of mastoid cells from these three cavities, which ceases between the fourth and the sixth year. (3) Further formation of cells, which continues throughout life.

Chertle's researches go to show that the acellular structure of the infantile mastoid is diploetic tissue, the only cells in addition to the tympanic antrum being a layer on its outer wall. It is stated that this acellular type persists throughout life in 15 per cent of people. In the second type (cellular or pneumatic) the diploe is replaced by an spaces which have extended from the middle-ear tract. Between the infantile acellular diploetic mastoid and the cellular or pneumatic mastoid several intermediate varieties of bone are recognized. In the adult bone these represent an arrest of development corresponding with a definite age in the child. This is of special interest in the consideration of asymmetry in the mastoid and its possible etiology.

In the standard x-ray projection we can trace the gradual pneumatization and the approximate normal for the age. The standard projection used gives practically a lateral projection, and the following landmarks should be studied and recognized. We first of all recognize the external and the internal auditory meatus, just a little superior and posterior to this is located the mastoid antrum. Directly posterior to the canal at a variable distance is the groove for the sigmoid sinus. Passing downwards and forward through the mastoid process to the jugular fossa—below and in front of the mastoid tip—the sharp angle or knee of the sinus groove can be recognized, and it is especially important to note the anterior line of this groove. Below this is the tip, and just behind the canal is an opaque area forming the posterior meatal wall with the facial nerve underneath. Above the mastoid antrum and middle ear can be seen the tegmen of middle ear and antrum. The superior line of the squamous may be indicated. In front of the meatus we have the temporomandibular articulation with the glenoid cavity and the condyle of the lower jaw. Frequently the emissary vein is seen as a worm-like shadow situated anywhere between knee and tip. The area enclosed between the posterior meatal wall in front, the tegmen above, and the anterior wall of the sinus groove forms roughly an inverted triangular area, with the tegmen as base, for descriptive purposes this has been called the triangular area.

Returning to the radiographic studies of the normal mastoid in children, this is found to correspond more or less closely with Wittmack's stages of mastoid pneumatization. (1) From birth to one year the only cell development is seen in the mastoid antrum, which occupies a more superior position to the auditory meatus than in the adult and is of comparatively large size. (2) From the first to the sixth year cell development begins and is confined to the triangular area previously described and forward towards

the zygoma in some cases. (3) From the sixth year to the sixteenth we notice gradual cell development beginning posterior to the inferior sinus groove, starting first at the lower posterior part and tip. (4) The complete pneumatization extends eventually to the upper posterior part and permeates completely the mastoid process.

The pneumatic mastoid in the adult may show cell development corresponding closely to these four stages. Another feature of interest is that cells laid down early in the triangular area are smaller as a rule than those developed at the tip and posterior part of the mastoid later, this is well shown in some of the radiograms.

### Symmetry of Mastoids

By symmetrical mastoids is meant that they are either both pneumatic or both diploetic in structure. Asymmetrical mastoids would thus mean a diploetic mastoid on one side and a pneumatic mastoid on the other, a case revealing an extensive pneumatization on one side with a very limited pneumatization on the other is not in the true sense an illustration of asymmetry, but rather symmetrical mastoids with arrested pneumatization on one side.

In their investigations Beck, Law, Ravichon, and others report consistent symmetry. Turner and Porter, in their examination of 1,000 crania, report 12 per cent asymmetrical. Plum suggests that some of these might possibly indicate arrested development. With regard to the present series, in the normal cases I have examined I have found the mastoid processes consistently symmetrical. Where there was no ear complaint and the x-rays revealed apparently asymmetrical mastoids, investigation has shown without exception the presence of either a mastoiditis or a healed condition, often previously unknown to the patient. Thus apparent or false asymmetry due to some previous pathological condition is a very common occurrence.

We now come to the question of the influence of an inflammatory process on mastoid development and thus indirectly on the question of asymmetry.

Macewen in 1893 stated that "In chronic cases of inflammation of the mastoid an osteoplastic formation may be set up in the neighbouring bone which results in an abutting sclerosis and an actual obliteration of many of the mastoid cells." This well expresses the old view regarding the sclerosed mastoid frequently found at operation.

Chertle has more recently stated that in infancy, with the exception of the mastoid antrum and a few cells on its outer wall, the mastoid consists of diploetic structure, further, that this so-called infantile type persists in 15 per cent of people. Chertle's researches tend to show that the sclerosis produced at first round the antrum is not the effect but the cause of the chronic suppuration, the cellular condition being thus primary. Wittmack, on the other hand, believes that hyperplasia of the mucosa with incomplete or arrested pneumatization is caused by the entrance into the tympanum of amniotic fluid, meconium, etc., during foetal life or at birth, or the entrance of vomitus during the first year of life. Wittmack's theory is supported by Preece and others.

As I have already stated true asymmetry has not been found in the present series of cases—that is, apart from a previous pathological condition of the mastoid. In addition, I have not been able to find a case presenting normal ears with a sclerosed or ivory mastoid. Assuming Wittmack's theory to be correct regarding the production of the acellular type of mastoid, I have found the acellular mastoid to give the x-ray appearance suggesting a diploetic mastoid rather than a sclerosed mastoid. Law in 1920 stated that it was impossible to distinguish between a sclerosed mastoid and a diploetic one.

In the present series of films I have found that the appearance of a sclerosed mastoid is different from that of a diploetic one. Further, cases of chronic mastoiditis on x-ray examination reveal all degrees of thickening of the cell trabeculae, in some cases so thick that the mastoid cells are almost obliterated. This thickening is shown only in the cases of healed mastoiditis, whereas in the normal pneumatic mastoid the trabeculae are of a very uniform degree of fineness and the cells distinct and well marked.

\* A paper communicated to the Section of Laryngology and Otolaryngology at the Annual Meeting of the British Medical Association, Edinburgh, July, 1927.

Taking the cases where a healed mastoid was found it can be demonstrated that the inflammatory process has undoubtedly produced an arrest of pneumatization on the affected side as compared with the healthy, the subsequent growth of bone in these healed cases being apparently diploetic in structure as distinct from the ivory sclerosis found in some cases of chronic mastoiditis. This arrest of pneumatization in the adult I have been able to demonstrate as corresponding to the various stages previously mentioned in the normal pneumatization process in the child.

Taking the present series as a whole normal and abnormal, I have found true diploetic acellular mastoids to be comparatively rare whilst those showing arrested development are of frequent occurrence. I have come, then, to the following conclusions from the cases studied:

- (1) That normal mastoids are symmetrical
- (2) That they are of two types (a) pneumatic or (b) diploetic. Apart from chronic mastoiditis never of the ivory sclerotic type
- (3) That arrest of pneumatization occurs following otitis media with mastoid involvement, many cases of apparent asymmetry are due to this cause
- (4) That the normal pneumatic cases far outnumber the normal diploetic.

#### The Value of X Rays in Mastoiditis

Kutner as recently as 1912 stated that radiology did not furnish any assistance in otology. Winckles and Voss on the other hand, in 1907 reported x-ray findings verified by operation. Plagmann, by means of a negative, was able to distinguish whether the disease was confined to mucosa in an acute case or whether there was some bone caries. Law in 1920 produced a descriptive atlas including operation findings and technique. Plum in 1924 gave a record of x-ray procedure with confirmed operation findings.

It would be well to emphasize at once that as in other branches of medicine and surgery the diagnosis should not be attempted on x-ray findings alone but, if properly studied and applied we have a very valuable addition to our other clinical means of investigation.

At the throat and ear clinic of the Royal Infirmary, Glasgow we have employed this method to all possible cases of mastoiditis acute and chronic coming to operation. It has thus been possible to compare the x-ray and operation findings. The initial difficulties were many.

If radiography is to be of any use as a routine method several things are, in my opinion, essential. The first essential is to decide on a standard position. Next it is necessary to become familiar with the normal appearances at different ages, and the various results of pathological processes. Good plates, indeed very good plates, are essential. The following have been selected: (1) A large series of normal mastoids child and adult. (2) A series of pathological conditions in children. (3) The conditions seen in a series of 50 operations with the x-ray findings noted. (4) A series of cases illustrating other conditions—for example, simple acute otitis media, furuncle of meatus etc.

Plum (1924) has suggested that an x-ray photograph does not reveal whether disease is active or healed and that only repeated negatives during the process of disease give indication of active lesion. It is undoubtedly the case that, taking negatives alone, this may be true and also that repeated negatives may be considered in acute cases, but, if the other clinical observations are combined with a single x-ray plate a fairly accurate opinion may be given regarding conditions in the mastoid. It has also been stated by various authors that x-ray findings in cases of chronic suppurative otitis media are of less value than in acute cases. It has been possible however to demonstrate from the present series many interesting and suggestive changes in chronic cases verified by operation.

#### X-Ray Appearances in Normal Mastoids

The characteristics depend on the type being examined. A radiogram of both sides should be obtained on the one plate for comparison. This is especially valuable in unilateral cases. If bilateral, the surgeon must compare with what he would assume to be the normal condition at the age of the case under review.

Dealing first with the mastoid with arrested cell development at some period under 6 years of age, we can distinguish the following features: (1) the auditory canal, (2) the posterior wall of the bony meatus (3) the sinus groove, especially the anterior wall, (4) the line of the tegmen of the antrum (5) the tip of the mastoid process. The only cell development noticed here is in the triangular area. The sinus groove is usually well seen, but the antrum is indistinct. The remainder of the mastoid is usually diploetic in structure.

**The Diploetic Mastoid**—This shows all the features of the above except cell development in the triangular area. The mastoid throughout being of uniform fine meshwork, much finer than in the smallest pneumatic mastoid. Only a very good film will show the true nature of the diploetic structure.

**The Pneumatic Type**—Primarily, although the size of the cell may vary in individuals, the smallest cells are found in the triangular area whilst the largest are in the tip and posterior to the sinus groove. These latter cells are developed later. The cells frequently run well forward into the tegmen. Another important point in the normal pneumatic mastoid is the character of the lines indicating the anterior sinus groove. This line sometimes shows clearly, at other times only faintly. This depends on the thickness of the sinus plate compared with superimposed cells. It has already been stated that normally the mastoids of any particular case are symmetrical. This not only applies to the type of mastoid but to the size of the cells where there is a large cell or collection of cells in one situation, a similar collection is usually seen in the same situation on the other side. This makes it possible to distinguish sometimes between an area of cell development and an area of caries with bone absorption. The size and position of the emissary vein should be noted as a matter of interest.

**The Sclerotic Type**—This I have only found associated with a chronic process in the mastoid. Often no cell outline can be distinguished but, as sclerosis is not always uniform, areas of caries with bone absorption can be noticed. The anterior sinus groove is often well marked.

From the series of x-ray findings followed up to operation I have been able to verify the following conditions:

- 1 Hypoaemia of mastoid cells in acute otitis media without obvious mastoid disease
- 2 Acute mastoid inflammation
- 3 Purulent mastoiditis
- 4 Caries indicated by breaking down of cell trabeculae in pneumatic mastoids or areas of bone absorption in previously diploetic or sclerotic mastoids
- 5 Exposure of sinus extradural perisinus abscess
- 6 Exposure of middle fossa dura with low middle fossa
- 7 Cholesteatoma
- 8 Sclerosis with often a sinus groove unusually far forward. This condition gives more or less definite x-ray appearances.

**Mild Acute Mastoiditis**—The diseased side in pneumatic mastoids shows a faint haze covering the mastoid, as compared with the clear outline of the healthy side. The cell trabeculae are still distinctly seen. I have found that this haziness is especially marked in the region of the mastoid antrum. A case presenting these features, with free drainage should be left alone providing other signs do not indicate operation. Where, because of cessation of discharge, increase of pain in the ear with elevation of temperature, etc., operation has been undertaken, the mucous lining of the cell is found to be oedematous, a collection of haemorrhagic serous fluid is found in the mastoid antrum but there is an absence of caries or pus. Sydney Lange records this degree of mastoid involvement in 50 per cent of cases of apparently simple acute inflammatory otitis media.

**Acute Purulent Mastoiditis**—In these cases the cells are filled with purulent discharge. There is a greater degree of cloudiness of the cells especially in the triangular area, obscuring the antrum. The sinus groove is well marked. Such an appearance may be associated with symptoms or signs indicating operation. I have found beads of pus throughout the mastoid, the mucous membrane oedematous, and, on opening the antrum, a collection of pus, there is no breaking down of the cell trabeculae.

**Severe Purulent Mastoiditis, Acute or Chronic**—The pneumatic mastoid here appears entirely blurred. Areas of apparent rarefaction consequent on the breaking down of cell trabeculae or cysts indicate the necessity for operative measures, and at operation extensive cysts may be found with collection of pus especially surrounding the antrum or towards the tip, these areas, however, may be found at any point in the mastoid. Up to the stage of cysts the line of the anterior sinus groove is intact and more visible than in the normal side, but where the sinus plate is affected the intact line becomes broken, and at operation the sinus is seen to be exposed and sometimes covered with recent granulations—granulations and pus being found throughout the mastoid. An x-ray plate with the above findings indicates immediate necessity for operation apart from the presence or absence of such signs as temperature, mastoid oedema, tenderness, etc. In several operation cases I have been able to demonstrate abscess formation in acute and chronic suppurative mastoiditis in the x-ray films. In these cases the cell trabeculae break down and numerous cells appear to have coalesced, the outline of the abscess being sometimes clearly marked. Frequently in these cases the lines of the tegmen and of the anterior sinus groove become broken or blurred, and operation has revealed extracranial, middle fossa, and petrous abscess. A common situation for abscess formation is in the large tip cells.

The edges of an area of bone formation corresponding to an abscess are often blurred and hazy, but readily distinguishable. It has been noted in some cases that the area of maximum tenderness corresponds accurately to the area showing bone absorption. Cholesteatoma formation occurring in chronic cases sometimes presents a diagnostic picture of an indefinite haziness, this is usually surrounded by an area of increased density, the surrounding bone having undergone osteoplastic change resulting in ivory-like sclerosis. The condition is most commonly noted in the triangular area surrounding the antrum. The density of the shadow found in cases where operation has revealed ivory sclerosis has, in my experience, never been seen in the mastoid process of the normal ear, in the presence of a chronic discharge, indeed, this type of change is a distinct indication for a radical mastoid operation, as there is little chance of a permanent cure.

There are several other conditions where x-ray evidence is of great assistance in diagnosis.

(1) **Mailed Dermatitis or Eczema**—Frequently cases occur of eczema or dermatitis of the external auditory canal with stenosis, in these, because of their chronicity, a middle-ear origin is suspected. The x-ray picture in some of these cases pointed directly to the mastoid as the source of infection, whilst in others a beautiful healthy pneumatic mastoid has been found, absolutely excluding mastoid disease.

(2) **Furunculosis**—With post-aural infection and oedema the x-rays have again given valuable diagnostic assistance and sometimes prevented a mastoid operation. In these cases a haze is apparent over the mastoid, but there is no indication of cysts. The employment of routine x-ray examination of mastoids of all cases of otitis media enables us to decide whether conservative measures—for example, removal of polyp, ionization, douching, drops—are likely to prove satisfactory. I have found in this way cases with chronic aural discharge, but no other symptoms where radiography has revealed cholesteatoma or dural exposure.

#### Conclusions

- 1 Mastoids are normally symmetrical
- 2 Mastoids are usually pneumatic, occasionally diploetic
- 3 Nothing has been found to disprove Wittmach's views of the origin of the diploetic mastoid
- 4 Pneumatization proceeds in a more or less definite manner in children normally, mastoiditis, mild or severe tends to arrest cell development, resulting in the persistence in adult life of a partially pneumatized mastoid process
- 5 If reinfectied this arrested or infantile type of mastoid may develop a sclerotic character, and is probably more liable to chronicity

6 A dense sclerosed mastoid has not been demonstrated without at least evidence of a pre-existing otitis media

This investigation has been carried out in the throat and ear clinic of the Royal Infirmary, Glasgow, under the charge of Mr James Harper. The operations were performed by Mr Harry Dr. Leitch, and myself. I am indebted to Mr Harper and Dr Leitch for the operation findings in their cases and for permission to include them in the present series. I desire also to express my indebtedness to Dr Bruce MacLennan, our radiologist, and his staff for the very considerable trouble taken with the x-rays. I am also indebted to Dr Logan Turner and Dr Fraser of Edinburgh for very valuable references.

### MEDICAL, SURGICAL, OBSTETRICAL

#### PULMONARY EMBOLISM WITH KNOT FORMATION IN THE CLOT

This accompanying photograph shows the appearance of an embolic clot found at the bifurcation of the pulmonary artery in a patient who died suddenly with the usual symptoms of pulmonary embolism. The clot, when found was not spread out as in the photograph, but lay curled up at the bifurcation of the pulmonary artery, it extended a little into the right pulmonary artery, and a very little into the left pulmonary artery. The only true knot, however, was the one illustrated. The total length of the clot is almost 17 in.

A possible clue to the knotting is provided by the unusual site of origin of the clot. This was in the left axillary vein. A more angled path to the pulmonary artery had thus to be followed than is the case with the more common clots coming by way of the inferior vena cava from the pelvis or leg veins. The clot may thus have been intruded for some time when only part had passed the transpericardial valve, and the portion in the ventricle may have been knotted by the repeated contraction of that chamber, particularly if the part still lodged in the transpericardial orifice was causing some incompetence at the same time, and so modifying the blood currents in the ventricle. The history tends to support this view, for the patient lived for nearly an hour after the pain in the chest and respiratory distress commenced, and then died suddenly. He was a man aged 56, and was suffering from an ulcer of the left axilla, resulting from neglect of a slight wound of the hand. The wall of the axillary vein was inflamed and surrounded by pus. The femoral and pelvic veins were healthy.

I have to thank Mr J. Mainoch, professor of surgery, Aberdeen University, for the notes of the case, and Professor Sherrin, of the Pathological Department, for permission to publish this report.

JOHN CLAY, M.B.

Pathology Department Aberdeen University

#### ACUTE VERONAL POISONING WITH TOBAC PNEUMONIA AND BILDSORIC

The following case of veronal poisoning which occurred in my practice in Valparaiso, Chile, this year, four months before I left for England, seems worthy of record in view of the large dose taken and the subsequent complication which delayed recovery.

I was summoned urgently one night at about half past ten to see a woman who had taken an overdose of veronal and died fifteen minutes later. I found her deeply unconscious. She had been given some hot water and had vomited a little brown fluid. The pulse was regular and the colour good. The patient reacted normally. I washed the stomach out with warm water containing sodium bicarbonate until the solution became clear. The first returns being brownish and containing some tablets. I gave her a tablespoonful of sodium sulphate in half a pint of water and left in the stomach. Hypodermic injections of atropine, digitaline, caffeine, and camphorated oil were given at intervals.

At 7 o'clock the next morning the patient had a prolonged rigor and during the day there was a rise of temperature the bowels acted well. The stomach was again washed out in the evening when the temperature was over 102°. Signs of consolidation were found at the right base the pulse had increased in rapidity and the respiration was short and quick. On the second morning there was definite lobar pneumonia involving the lower two-thirds of the right lung there was no cough but tracheal rattling was very distressing and the mucus had to be removed at frequent intervals from the throat and mouth. The patient was fed through a tube at eight hourly intervals and oxygen was administered every half hour for about five minutes each time. The urine which contained a trace of albumin but no sugar was drawn off every eight hours. At midday 25 ccm of polyvalent antipneumococcal serum were injected. That evening the temperature was over 104° and the pulse 150 the patient was kept in the sitting position.

On the third morning her condition was grave and a red patch had appeared on each buttock. The temperature fell somewhat in the evening but rose again the next morning when some slight movements of the eyelids were evident and there was a little resistance in passing the stomach tube. During the following night some movements of the facial muscles began and the patient became able to swallow a little water. Though still unconscious on the fifth day the patient was able to swallow more easily and the lung began to clear. Later in the day she began to talk wildly and it was not until the following evening that she became more or less rational.

On the seventh day the dry rub of pleurisy was evident behind her left shoulder but this disappeared in a few days as also did the pneumonia. On the eighth day a buttock abscess was incised under ether. On the eleventh day giant urticaria developed with intolerable itching the pain and rash were relieved by hot alkaline applications and occasional subcutaneous injections of 2 to 3 minims of adrenaline.

After another four days the patient was obviously convalescent except for the bed sores. The sloughs gradually separated leaving large cavities on each buttock which extended for four or five inches in the direction of the ischio-rectal fossae daily boracic baths being much appreciated by the patient.

The amount of veronal taken by the patient was estimated at 15 grams or 225 grains but about 25 grains were probably left in the cup used. Complete unconsciousness lasted for a period of 115 hours after which it took the patient at least two clear days to realize fully the gravity and nature of her illness.

The quantity of the drug taken, with subsequent recovery is in itself worth recording but the various complications add further interest to the case. The bed sores would most probably have been avoided had trained nursing been available but it is possible also that so large a dose of poisonous reagent in the system only requires a determining factor such as pressure for a certain number of hours to induce gangrene of the tissues. So far as I can remember the patient weighed only about 7 to 7½ st.

London

### A TREATMENT OF MORPHINISM

It is universally maintained that the eventual outlook for the morphine addict who submits to treatment is very bad indeed the rate of permanent recovery being variously estimated as between 10 and 15 per cent. Furthermore the process of withdrawal is reputed to be exceedingly painful in whatever manner it is performed.

I am now able to give the after history of ten consecutive patients who were treated by a somewhat elaborate technique whereby the usual discomfort is avoided. With this series the average duration of addiction was eleven years and all except two had been treated unsuccessfully by other methods. The average length of treatment was exactly thirty days or which about half were devoted to withdrawal. The treatment of the various individuals was spread pretty evenly over the three years ending last June and the result is accurately known in every instance.

Of these ten patients, nine have remained without any sort of relapse since they were dealt with. The tenth had to face prolonged domestic unhappiness and morphine was restored as the only means of procuring sanity. I am not aware that any other method can show results which are at all comparable.

A full description of the technique appeared in the *Practitioner* of January, 1927. The reduction of morphine is covered by two waves of overdosage by drugs or the atropine group and by luminal respectively in such a way that morphine is timed to be completely withdrawn just before the maximum doses of luminal are administered. Use is made of the "special mixture" of Lambert (tinct. belladonnae, liq. ext. hyoscyami et scopolami ad 5j) Lambert's

method aims at the rapid withdrawal of morphine, and produces a mild delirium which in some instances deadens the sufferings of the patient. The present method secures a much higher tolerance of atropine, which appears to be the factor which renders withdrawal painless. Indeed, it is not too much to say that as skill is developed in meeting the various emergencies which may arise, the majority of patients can pass through the treatment without an hour of uneasiness. A very important factor in attaining this result is the cautious manipulation of the doses of the habit-forming drug. Small supplementary amounts are kept in readiness so that the patient is not allowed to suffer. In practice, a certain degree of atropine tolerance seems to enable a given level of withdrawal to be painless; as tolerance develops this level gradually sinks, and the patient remains perfectly comfortable so long as rapidity of reduction is kept within this limit. While such elaboration of technique adds greatly to the trouble expended upon each individual case, I claim that the patient's comfort is well worth securing. It would seem, also, from the after-history of the small series referred to, that the more important question of permanency is very favourably influenced.

London W. 1.

### FOREIGN BODY IN THE BLADDER

THE following case of a foreign body with secondary phosphate calculus imbedded in the urinary bladder is worthy of record.

A girl aged 11 was sent to me for cystoscopic examination with a tentative diagnosis of renal tuberculosis.

She had been seen four weeks previously by her doctor to whom a history of three months incontinence of urine was given. He found her suffering from pruritis and albuminuria and as no improvement took place under medical treatment a tuberculous infection was suspected and a further investigation was advised.

The child appeared to be very ill and toxic. I could obtain no definite history from her or her mother as to how the condition started. The child struck me as being unusually shy and secretive and of rather dull intellect for her age. The tempera-

ture was 105° the pulse 34 and the respirations 35. Micturition was frequent but painless. Complaint was made of a dull ache in both lumbar regions and there was tenderness on palpation over the hypogastrum. The urine was foul and alkaline albumin and pus were present in large quantities and casts were seen under the microscope.

I suspected a foreign body of some nature in the bladder. X-ray examination revealed a hairpin encrusted with phosphatic material with the points directed towards the base of the bladder (see photograph). I removed the hairpin through a suprapubic incision and washed out a considerable amount of foul phosphate debris. Suprapubic drainage and daily lavage cleared up the condition and the wound closed in three weeks. The urine was then quite clear free from casts and normal in every way.

GUY CHAMBERS, F.R.C.S.

Honorary Surgeon, Isle of Wight County Hospital.

### THE USE OF QUININE BIPHENYLDROCHLORIDE IN OBSTETRICS

SINCE Dr S. Gordon Inker recommended the use of quinine biphenyldrochloride in the treatment of puerperal pelvic infection I have employed it with success, though the number of cases is too small to justify any dogmatic assertion. Since the injections can be made after effects this treatment should follow I think every difficult labour. I append a short note of two cases.

A primipara more than 30 years of age was delivered after a difficult instrumental labour in which I had no help at all. Twenty-four hours later she had a rigor so severe pains in the head and abdomen and a temperature of 104°. I gave one injection and the temperature had fallen to 99° by the next day. There was no further trouble and she was able to suckle her child. A primipara not seen till 1½ hours in labour was found to have fibroid which obstructed delivery. Caesareanotomy was performed under most adverse conditions. One injection of quinine was given immediately after delivery. The temperature rose to 99°.

and the pulse to 100, on the fourth day, but the patient was perfectly comfortable throughout the puerperium and was able to rise on the ninth day.

Other instances could be cited. Since the injections are painless I venture to think that it is well worth while to employ this treatment whenever it has been necessary to intervene in the course of labour. The dose is 5 grains and the injection should be made into muscle.

O STEEL, L.M.S.S.A.

## Reports of Societies.

### RECENT ADVANCES IN TOXICOLOGY

At the meeting of the Medico-Legal Society on October 27th Sir WILLIAM WILCOX, the new President, delivered his address from the chair, which was chiefly a review of recent advances in toxicology.

After some reference to the history of the Society and the value of its work he pointed out how necessary it was in forensic medicine to eliminate all possible risks of fallacy in the scientific tests employed, and paid a tribute to the work done in chemistry, physical chemistry, and physics, saying that most of the new methods and tests used in medico-legal science were really the application of principles already worked out in the pure sciences. But in forensic medicine the practicability of a test had also to be considered. Scientific research from time to time elaborated new and important tests, but their practical application in medico-legal investigation was not always easy. The recent work on the examination of alcohol in the urine as a guide to alcoholic intoxication, for example, was important, but it was not easy to see how this work could be applied in police court cases.

With regard to toxicological advances, he instanced, in the first place, the work on arsenic. One of the latest advances in toxicology was the electrolytic test for the detection of minute quantities of this poison. This superseded the use of zinc, which had been necessary in the earlier tests, and which always left a doubt in the mind as to the possibility of arsenic appearing from some impurity in the metal. Platinum electrodes were now employed, or, in further modifications, said to be improvements, lead, mercialized lead, or mercury electrodes, but in any event the electrodes were now entirely above suspicion. The Seddon case was the one in which the electrolytic test was first used in determining quantitatively the amount of arsenic in the organs of the victim. In the Armstrong case, which was also one of acute arsenical poisoning, the interest arose from the fact that the arsenic would never have been suspected as the cause of death in the case of Miss Armstrong, who had already been dead for a year, had not Armstrong made an attempt to poison another person, who was given an approximately fatal dose of arsenic, and whose symptoms recalled to the doctor those which he had observed in the case of the woman a year previously. On exhumation it was found that a dose much larger than the fatal one had been taken twenty-four hours before death, and from its distribution in the body it could be said almost exactly when the fatal dose was given. Sir William Wilcox also mentioned that, five years ago, he was consulted by an Indian official who had come home on account of an obscure illness which could not be diagnosed in India. He cut off some of his hair and had it analysed, and it was found to contain traces of arsenic. The man was really suffering from arsenical poisoning, and the occasion of the poisoning was traced back to a date two months previously, before he left India, when his cook, under the influence of political agents, had endeavoured to assassinate him.

Sir William Wilcox then went on to refer to the arsenobenzol compounds. He said that since Ehrlich's discovery of salvarsan in 1910 innumerable arsenobenzol derivatives had been introduced, but none of them had proved superior in therapeutic value to the original salvarsan. The compounds had become definitely established as the most effective remedy for the treatment of syphilis, and had proved of great value in the treatment of other diseases, such as relapsing fever, also. But the introduction of this

powerful remedy was followed by some instances in which the drug was found to have a toxic action, and investigations showed the necessity for close inquiry into the purity of the preparations. He next spoke of liver poisons, and mentioned a fatal case of toxic jaundice which came under his observation during the war. The patient had worked at an aeroplane factory at Hendon. On examining the conditions obtaining at that factory, it was found that tetrachlorethane was one of the substances in which cellulose was dissolved. Experiments carried out on rats showed conclusively that this was the substance which must be incriminated, the rats submitted to the vapour showed incipient toxic jaundice, with degeneration of the liver cells, and definite signs of hepatitis. Immediate modifications were made in the ventilation of the factory, which reduced the danger, and shortly afterwards it was found that amyl acetate could be substituted altogether for tetrachlorethane, and there were no more cases of toxic jaundice.

One of the striking advances in toxicology had been the improvement in methods for extracting alkaloids from viscera. It was realized to-day how important it was to do this work in low temperatures, if the work was done at a temperature above blood heat the alkaloid was destroyed by hydrolysis. It was by attention to these details that in the Cuppen case hyoscyne was extracted from the remains, which had been buried for six months. He also touched on lead treatment for cancer, introduced by Professor Blair Bell. The value of this treatment was still *sub judice*, but a good deal of light had been thrown thereby on the toxic action of lead, and views on lead poisoning had to some extent been modified.

Turning to new drugs, Sir William Wilcox said that there was a tendency to-day, when a person was ill, instead of giving him good, old-fashioned remedies, to select for use some of the new and much vaunted drugs of foreign manufacture with which this country was flooded, and unfortunately these drugs were allowed to supersede the old and well tried remedies. The best example was the barbituric acid and veronal group of compounds. Their name was legion, and they were introduced on the market with glowing advertisements, and were said to be perfectly harmless. He was not going to say that these drugs were of no value, because if used properly they were of value, but they were dangerous and toxic drugs, and he had endeavoured to call attention to the need of care in their use. From 1905 to 1925 there were 257 cases of fatal poisoning from these drugs, and there appeared to be no sign of diminution, but, on the contrary, the numbers were likely to increase. Numerous cases of addiction to these drugs had also been recorded. Then, again, there were the new organic compounds for all sorts of conditions and diseases which were poured into this country, and many of which were really powerful toxic agents. He thought the public ought to be protected to a greater extent than it was. He was informed on good authority that fine chemical and proprietary remedies were imported into this country in enormous quantities from abroad, with little restriction as regards duty, and no other restriction, whereas, on the other hand, similar products of British manufacture were subjected to such hampering restrictions and duties as to render the exportation of British remedies impossible.

A drug recently employed was thallium acetate, which had the remarkable property, in carefully calibrated doses, of removing from the body all the hair which was under the control of the sympathetic system. He had seen serious effects ensue from taking a full dose of this drug, and it seemed as if the possibility of idiosyncrasy and severe toxic symptoms must arise. Was it wise to employ so powerful a drug in full doses for diseases which were not mortal? With regard to physiological principles used therapeutically, insulin was a very powerful substance, of which only a minute quantity had to be used under most perfect control. The question of the toxicological detection of substances of this class, adrenaline and so forth, for forensic purposes had not yet arisen. The toxicological detection of bacterial toxins for forensic purposes might be a field of work for the toxicologist of the future.

In conclusion, Sir William Wilcox touched upon a few advances in forensic medicine apart from toxicology. Advances had been made in the detection of blood stains,

and it was now possible to say from an examination of a stain from what human group as regards agglutinating properties the blood had originated. In rounds from firearms chemical analysis of the projectile used now enabled one to say, by examining the marks inside the barrel which left a definite impression on the bullet found, whether the discharged bullet was or was not fired from a particular pistol. The application of ultra violet light in forensic investigations promised to be of great value. By this means the fluorescent properties of certain substances often served for their immediate detection and different kinds of paper, for instance which were indistinguishable by ordinary light, revealed their differences under ultra violet rays.

## MEDICAL BILIARY DRAINAGE IN GALL TRACT DISEASE

At the meeting of the Section of Medicine of the Royal Society of Medicine on October 25th Dr VINCENT LYON of Philadelphia described the technique and usefulness of medical biliary drainage in gall tract disease illustrated by a cinematograph film. Dr A. F. HURST was in the chair.

Dr Lyon said that many questions of diagnosis and the most appropriate plan of management would remain unsettled until the existence of cholecystitis was recognized at an earlier stage. Disease of the gall tract and its treatment had been a controversial shuttlecock and closer co-operation between surgeons and clinicians was necessary. There was a stage in the disease when surgery was unnecessary and perhaps harmful, a stage when it was indispensable perhaps even for the saving of life and a stage in which surgical efforts had been exhausted and non-surgical measures alone were of service to the patient. There was need for better judgement in the selection of each patient for surgical, non-surgical or combined treatment, and for better team work. Dr Lyon then illustrated, with the aid of moving pictures, the passing of the duodenal tube and the procedure attending biliary drainage and duodenal lavage, including the microscopical examination of the specimens of bile obtained. He also claimed that apart from its value in the diagnosis of some forms of cholecystitis and associated gall-tract disease the procedure of non-surgical drainage of the gall bladder by the use of irrigations of magnesium sulphate into the duodenum had a therapeutic value in a large number of conditions. He declared that biliary tract drainage when properly performed was valuable in the treatment of relapsing cholangitis particularly when a cholecystectomy had failed to relieve, the condition could often be cured without resorting to secondary operations provided that there was no evidence of residual stone in the common or hepatic ducts. When proper judgement was used in the selection of cases many patients with quiescent cholelithiasis might be restored to satisfactory health by this means. In some cases of gall-tract disease and quiescent cholelithiasis when surgical intervention had been precluded the non-surgical drainage had been substituted with satisfactory results. Another condition which could be checked by this treatment was persistent post-operative ileus and vomiting which ceased, sometimes after the first few hours of drainage, and always in a day or two. Simple catarrhal jaundice usually cleared up promptly in from two to seven days after the obstructive blocks of mucus had been removed. Gall bladder and duct catarrhs with sub-infection could often be cleared up and more serious pathological conditions prevented. The cholecystitis which was a complication of acute fevers often responded favourably to the treatment. There was also a large group of patients from whom the gall bladder and appendix had already been removed, and who suffered from hepatic or intestinal toxæmia and gave vague histories of various disorders in the past. The patient, very frequently medical drainage, colonic irrigation and dietetics secured much better results than emolument or other drugs. In association with other measures some patients with chronic neuritis and arthritis had been greatly improved particularly joint cases in which there was some infection from the liver or intestine. In the group including typhoid carriers this

treatment had also been found helpful. Dr Lyon instanced several other conditions as likely to benefit, mentioning that in a few cases of non-traumatic epilepsy, especially in young adults, seizures had been greatly lessened in frequency and severity when this method was tried, although various drugs usually employed in such cases had failed to relieve. The fundamental truth to be realized was that gall tract disease was not always—perhaps not often—a clinical entity confined solely to the gall bladder and bile ducts. Often it involved the liver, pancreas, duodenum, intestine as well as the cardio-vascular system. The crux of the therapeutic problem lay in the proper selection of patients in the various stages of gall tract and associated disorders for whom proper surgical, non-surgical, or combination methods were adopted. Dr Lyon described certain vicious circles which operated in the continued ill health or relapses of the victims of chronic gall tract disease and the reasons which had led him, after having previously used the method of drainage only occasionally, with results which stopped short of success to apply it intensively, under suitable control.

Dr A. F. HURST said that for some years past he had been very much interested in Dr Lyon's method from the point of view of diagnosis. He had gained the impression that it was of the greatest value and enabled a non-surgical mild type of cholecystitis to be recognized when it had hardly been discernible before. This was quite a frequent condition and in his view one of the three most common causes of chronic dyspepsia. He doubted if Dr Lyon's method of treatment had as wide an application as was suggested. Some cases of catarrhal jaundice cleared up in from two to seven days even though this treatment had not been employed. With regard to the less radical methods of non-surgical biliary drainage, Dr Hurst added it appeared to be quite clear that the gall bladder would contract after magnesium sulphate had been given by the mouth and in many of the milder cases of chronic cholecystitis it seemed to him that the results of treatment of that kind had been admirable. With regard to the cause of infections of the gall bladder, his own experience was that the vast majority were due to aberrant forms of *B. Coli*. *B. staphylococcus* was hardly ever found. This however, was contrary to some observations at the Mayo Clinic.

Dr J. W. McCREE said that Dr Lyon's method, while largely followed in America had made slow advance in this country where there had been some advance in diagnosis but not in treatment. He thought that there was no doubt of the importance of the method in diagnosis, but he was inclined to think that it did not pass the therapeutic value which Dr Lyon had supposed. In certain cases it was no doubt, useful, but the method which he himself had employed was simply the administration of magnesium sulphate by the mouth.

Dr F. A. KNOTT described an investigation into the diagnostic value of this method which had extended to more than 400 cases. The results had shown that as a test it was thoroughly practicable. Just over three-fourths of the specimens were noted as satisfactory—that is to say it was possible to obtain contrast specimens of the duodenal contents which were relatively free from bile and of the gall bladder bile (dark green) after magnesium sulphate. It had not been possible in this investigation however, to distinguish as Dr Lyon had done between different sorts of bile the bacteriological tests were made on what was assumed to be gall bladder bile. Out of these 411 cases according to the clinical notes, just over 100 cases of cholecystitis were detected.

Dr A. C. COWDIS said he had used the method rather extensively for diagnosis. He had tried it also in treatment but without much success and the patients finally asked for surgical intervention. A combination of magnesium sulphate and pectone had furnished good results clinically, and was a simple method which could be tried in all these conditions. Injections of pituitrin were also said to have a certain action in provoking evacuation of the gall bladder.

Dr T. LEON BENNETT thought that Dr Lyon deserved thanks for reasserting the importance of the catarrhal factor in gall-bladder pathology, which had been overlooked in recent years. The sulphate side of the infection had

been emphasized too much, and Dr Lyon had done well to demonstrate that pathological changes taking their origin within the ducts and spreading upwards played a very real part in the picture of liver and gall-bladder disease. Dr Lyon had also made clear the importance of a more thorough drainage of the capillary tree than was usually accomplished. His own experience was that in the milder cases of cholecystitis very great apparent relief followed the oral administration of magnesium sulphate, olive oil, and other stimulants, so far back as the days of the Romans the therapeutic advantages of magnesium sulphate under such conditions were recognized. The sprays of Europe were perhaps the best testimony that a very definite benefit was to be derived from magnesium and possibly other salts in dyspeptic conditions.

Dr Lyon in reply, said that in the Jefferson Hospital many patients had pleaded to be kept on the battery diuretic treatment, even after it had been definitely decided that they ought to be treated surgically, because of the symptomatic improvement which made them unwilling to undergo operation. It was true that magnesium sulphate by the mouth had been given for centuries, yet many of the patients who came to the clinic in America were persons who had spent long periods in European spas. Olive oil also had been given therapeutically for many years by the mouth.

### THE EPIDEMIC CONSTITUTION

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine, held on October 28th, the President, Dr S. Moxon Corbett, F.R.S., in the chair, Dr E. W. Goosvenor read a paper entitled "The epidemic constitution."

Dr Goodall remarked that recent years had seen a revival of a doctrine which had apparently died out in this country not long after the middle of the nineteenth century. The doctrine of epidemic constitutions was not seriously discussed in the early days of the Epidemiological Society (now the Section of Epidemiology and State Medicine of the Royal Society of Medicine), although it was erroneously alluded to in 1863 and 1874 by Inspector-General Robert Lawson, and in 1893 by Dr J. F. Payne, who expressed himself as being "very sceptical as to the reality of any such phenomena." The latest reference in an English textbook of medicine appeared to be that of Bristowe in 1864. Recently Sir William Hamer and Dr F. G. Crookshank had resuscitated the doctrine, and the epidemic constitution had been referred to in an annual report of the chief medical officer of the Ministry of Health. The particular phrase "epidemic constitution" seemed to be due to Sydenham, although Sydenham, to some extent, derived the conception from Hippocrates. It was, however, an error to seek to identify the epidemic constitution with the "something divine" of Hippocrates. Hippocrates's word was *latetastasis*, and, unfortunately, the English word "constitution" had been used by translators to render not only *latetastasis* but also *phusis*. In Dr Goodall's view Hippocrates meant by the *latetastasis* of a season the state brought about by the concurrence of certain weather conditions. He invoked no mysterious agent to account either for diseases or epidemics. Galen made no advance upon the Hippocratic teaching, and although Prætorius provided us with another instrument of research when he very clearly explained the modes by which infection could be spread, no notable advance in our knowledge of the epidemic behaviour of diseases was due to him. Sydenham divided the prevalent epidemic diseases into two groups—the stationary and the intercurrent fevers, the former depended upon the epidemic constitution. The existing constitution not only determined what should be the stationary fever, but impressed its characters, which were manifest especially in the stationary fever, upon such intercurrent fevers, and even other diseases as happened to be prevalent at the time. Thus, during one period—1667 to 1669—the constitution was a virulose, and so small-pox was the stationary fever, but amongst the intercurrents prevalent during that constitution was a certain continued fever, and, towards the end of the period, a diphtheria also. In accordance with the

doctrine both these diseases exhibited some of the features of small-pox, without, however, the eruption. This was Sydenham's account of the manner in which an epidemic constitution made itself felt, but what he meant by the term "epidemic constitution" could not be ascertained, it was a vague something over and above the more obvious causes of disease, the presence of which was necessary to bring about an epidemic. Sydenham's new points were that the nature of the constitution varied from time to time, that it determined the prevailing epidemic and imparted its characters on concurrent minor epidemics, and even on diseases which were not necessarily epidemic at all. In this conception Sydenham was to some extent anticipated by Galeazzo di Santa Sofia in a book published in 1514. The most prominent modern supporters of the doctrine, Sir William Hamer and Dr F. G. Crookshank, had stated their views briefly but clearly in a work entitled *Influenza*, edited by Dr Crookshank and published in 1922. According to Dr Crookshank, by "epidemic constitution" "we really mean to imply all the correlated symptomatic disorders and their consequences manifested in a community or population during a period of time that is not arbitrarily selected, but has natural duration and limitation and during which peculiarities and occurrences of distinctive nature arise." In Dr Goodall's opinion this was rather a definition of what Sydenham meant by the stationary and intercurrent fevers, a prevalence of diseases brought about or influenced by the constitution, than a definition of the constitution itself. It appeared to Dr Goodall that upon this Dr Crookshank's view was much the same as Sydenham's, and consequently vague. Both Sir William Hamer and Dr Crookshank, "who started as followers of Sydenham, have far outstripped their master, and have now set out in quest of the cause not only of an epidemic, but of the cause of the cause of an epidemic, the cause of the veritable epidemic constitution itself." In Dr Goodall's view the revivalists had not helped us much towards understanding what Sydenham meant by the epidemic constitution, nor provided a satisfactory substitute. Dr Goodall had asked himself whether in his own experience the characteristics of the prevailing stationary fever were impressed upon the intercurrents. In particular, he had paid special attention to the cases admitted to the North-Western Hospital at Hampstead during the winter and spring of 1924-25. Influenza was the stationary fever of the period, whooping cough, scarlet fever, diphtheria, mumps, rubella, and chicken pox were the intercurrents amongst the infectious diseases. He had found no evidence whatsoever that these last-mentioned diseases bore any trace of influenza, and that experience was the experience of former years.

Dr Goodall rejected the doctrine of the epidemic constitution as set forth by Sydenham and the revivalists. He thought that the genesis of an epidemic was not dependent upon a single cause, nor upon one outstanding cause aided by minor causes, as Sydenham surmised. An epidemic was the result of the interplay of several factors, the kind and number of which varied with each disease. Any conception we might now have of an epidemic constitution or its equivalent could not be that of a single agent. Dr Goodall thought the term "epidemic constitution" should be abandoned altogether and replaced by Peters's "epidemic potential," with Professor Popple's extended definition—namely, "the balance of interacting forces which tends towards the occurrence of an outbreak of disease."

Sir William Hamer found Dr Goodall's paper stimulating, and recalled the respect in which Sydenham had regarded the Dr Goodall of his own time, perhaps in the star of his critic. Sir William regretted that Dr Goodall had not devoted more of his great clinical and epidemiological skill to the study of the interrelations of the various illnesses associated in time with influenza, and he pointed out that from the literary point of view there was no more than that from the literary point of view there was no more than Sydenham but really three Sydenhams, expressing the different developments of Sydenham's experience. Professor M. Greenwood agreed with Dr Goodall that the phrase "epidemic constitution" was misfelicitous. He agreed that Sydenham's theory was of no value. He thought, however, that the attempts of Sir William Hamer

and Dr Crookshank to show in order in the sequence of epidemics were significant although in his view, it was not likely that such attempts would be wholly successful until more had been learned by an application of the experimental method to herds of short-lived animals than from, of epidemiological problems less complex than those of human epidemics.

Professor W. C. COTTELL was in general sympathy with Dr Coddall, but thought that Sir William Hamer's criticisms of bacteriological interpretations had been very useful.

Dr J. D. ROLLSTON referred to some historical applications of the term "epidemic constitution." Fleet Surgeon W. E. HOME thought it was really impossible to form any clear idea of what medical writers of the eighteenth century really did mean, and that the use of vague indefinite terms had done, and might do, considerable harm.

The discussion was closed by the President, who congratulated Dr Coddall and the Section on the paper and the discussion it had provoked, and Dr Coddall himself replied.

## Reviews.

### ENDOCRINE GLANDS

THE combination of early physiological work, clinical experience and wide reading has enabled Dr W. JACOBSON Brown to write a clear and philosophical handbook full of suggestive ideas on the difficult subject of *The Endocrines in General Medicine*. Attractive from its potentialities and therefore open to rash speculations in the armchair, the therapeutic use of endocrine preparations is much in need of such an authoritative and well considered opinion, which strikes a judicious mean between the keen clinician and the cautious if not agnostic physiologist. Thus while sceptical about the uses of thymus, pineal, prostate, placenta, and mammary gland, he is favourably impressed with the future utility of gonad extracts. The methods of preparation and administration of the extracts, which have such an important bearing on the results, are, of course, discussed and there are useful comments on the dosage and therapeutic scope. The endocrine balance and the pluriglandular syndromes are naturally mentioned, and there is a useful table showing the types of disturbed endocrine balance in childhood, thus overactivity of the anterior lobe of the pituitary is held to be responsible for gigantism and for hemi hypertrophy, whereas its deficiency accounts for the Lorrain type of infantilism. But in the second edition, which will certainly be called for soon, a more extended discussion in a special chapter of that difficult problem of the pluriglandular syndromes would be a welcome addition.

The chapter with the rather arresting title "The retarding glands" deal with the thymus and pineal, which delay sexual maturity in the interests of more prolonged somatic development presumably by influencing in some way the endocrine balance, though there is not any evidence that they provide an internal secretion. Prophylactic measures in children thought to have status lymphaticus are suggested and the rare syndrome of macrogenitosomia praecox characterized by premature psychical, physical, and sexual development is ascribed to pineal defect. Elsewhere the adrenal cortex is regarded as a retarding agent in normal childhood defect being responsible for progeria, and overaction as in hyperplasia and tumour for virilism. This delicate discrimination between the contrary effects of normal and pathological activity of the cortex on development is of considerable interest. The clinical manifestations of hypothyroidism receive full attention, and reference is made to the rheumatic character of some of them, the explanation being that they are really due to myxoedematous infiltration of ligaments and fasciae.

There are many other interesting points to which attention might well be called, but enough has perhaps been said to show that this is a book to read.

### THE SCIENCE AND PRACTICE OF SURGERY

To attempt to cover the whole of the science and practice of surgery in two volumes of reasonable dimensions is an ambitious project. In their book on *The Science and Practice of Surgery*, Mr W. H. C. POMAN and Mr PHILIP MITCHENER, both of St Thomas's Hospital, greatly daring, have essayed this task with the intention of placing before the student a textbook sufficiently comprehensive to enable him to negotiate the higher examinations of surgery and at the same time providing the medical practitioner with a work of reference.

They have very nearly brought off a great success, for the book is well balanced, and includes chapters on such subjects as diseases of the eye, ear, nose, throat, as well as very useful articles on inflammation, sterilization, bacteriology and immunity.

The various sections, many of them written by specialists in the several branches, present a good deal of uniformity of style, and what perhaps is more important, the amount of room devoted to individual subjects bears a reasonable relation to their respective importance.

It is, of course, obvious that in an enterprise such as this insuperable difficulties must present themselves in steering a course between the dogma which is necessary and desirable for students and the more elastic discussion of pros and cons that one expects to find in a work of reference. On the whole the balance between the two is well maintained, learning if anything a little in the direction of dogma which no doubt is wise, as student readers may be expected to be in the majority.

With regard to arrangement, the general principles of surgery are considered in the first volume, and in the second regional diseases and their treatment are carefully described each section being prefaced by an account of the surgical anatomy and the physiology of the region or organ under consideration.

The illustrations are extremely numerous, but vary in quality, for some are exceedingly good while many are distinctly bad. It is difficult to understand the value of retaining such examples as Figs. 2, 15, 21, 26, 27, 50, 55, 94, in the first volume, and several others of similar character in the second.

No doubt they will be improved in a later edition, which will certainly soon be called for. Probably the authors will take that opportunity of amplifying the description of such subjects as post-operative thrombosis, gun-shot wounds of the bones, Cushing's work on the pituitary, the injection treatment of varicose veins, the treatment of hernia by fascial grafts and other sections that appear to have received less adequate consideration than might be desired by at any rate the post-graduate student. No doubt also the authors will by that time have informed themselves that their undue pessimism as to the value of radium in the treatment of cancer of the tongue (p. 197) is hardly justified by the facts.

There is a good table of contents in each volume and an excellent index, but there is no indication in either volume as to what is to be found in the other, the value of the complete work might be considerably enhanced were a composite index for the whole book to be included in each volume, together with a table of contents showing the general scope and arrangement.

### "THERAPEUTIC MALARIA"

THE employment of an artificially induced malarial infection as a therapeutic agent has become so widespread in recent years that such an account as Dr RUDOLF has given of its technique, results, and possible complications in his *Therapeutic Malaria*,<sup>2</sup> will be widely welcomed.

Only a few years ago general paludism of the type was regarded as a necessarily fatal disease with a duration,

<sup>1</sup> *The Science and Practice of Surgery*. By W. H. C. POMAN, M.A., M.B., M.Ch. Cantab., F.R.C.S. Eng., F.R.S. Ed. and Philip H. MITCHENER, M.D., M.S. Lond., F.R.C.S. Eng., Vol. I. General Surgery. Vol. II. Regional Surgery. London, J. and A. Churchill, 1927. (Pop. 8vo. Vol. I. Pp. viii + 725. 650 figures. 9 plates. Vol. II. Pp. viii + 550. 250 figures. net £5 a volume.)  
<sup>2</sup> *Therapeutic Malaria*. By G. M. RUDOLF, M.R.C.S. L.P.C.P., D.P.H., D.P.M. Oxford Medical Publications. London. Oxford. Oxford University Press, 1927. (Demy 8vo. Pp. xi + 223. 55 figures. 2 plates. 12. 6d. net.)

<sup>1</sup> *The Endocrines in General Medicine*. By W. JACOBSON BROWN, M.D., D.Sc. F.R.C.P. London. 80 pp. viii + 127. 6d. net.

generally, of from one to three years, a disease in which there was little prospect of betterment beyond the possible occurrence of a temporary halt in the march of its progress towards paralysis, dementia, and death. Since the introduction by Dr Wagner-Juregg of Vienna of malarial therapy a complete change has been wrought in the attitude of physicians towards this disease, and at the present day a case of general paralysis is one which requires and receives vigorous treatment, by far the most hopeful form of which is that by inoculation with benign tertian malaria.

Dr Rudolf is an assistant medical officer at Claybury Mental Hospital, London. It was in the summer of 1923 that his chief, Dr G. F. Baillam, decided to introduce malarial therapy at this hospital—time when this mode of treatment was still in its infancy. Dr Rudolf has therefore had ample opportunity, of which he has made full use, to study the course of general paralysis as influenced by malarial infection, and to make observations of its sequelae over a length of years.

Dr Rudolf, like, we believe, all others who have used this treatment, is of opinion that the earlier the case of general paralysis is treated the better the prognosis, and quotes Wagner-Juregg as saying that if only early cases are treated nearly 100 per cent of remissions can be obtained. Interesting evidence is also provided of the value of malarial therapy in tabes and neurosyphilis, and cases are quoted of syphilitic cerebral thrombosis treated at Claybury Mental Hospital with marked improvement.

It was to be expected that a method of treatment which had produced such striking results in general paralysis should be tried on other forms of mental disorder. Wagner-Juregg had reported an early acute case of dementia praecox as apparently cured after treatment. Dr Rudolf has observed that his cases of dementia praecox at Claybury, whilst showing temporary benefit as the result of this treatment, soon afterwards relapsed into their former state.

The author takes care, in discussing the mental changes that occur during the malarial treatment of general paralysis, to keep in mind the mental aspects of both diseases, malaria and general paralysis. Some patients developed auditory hallucinations after the fever, and these persisted for many months. Dr Rudolf considers this to be due to the general paralysis and not to the malaria, although hallucinations are considered rare in the untreated disease. The mental and physical and pathological changes occurring as a result of malarial treatment receive full consideration. The author's discussion of the technique employed is succinct and reliable. The various safeguards against the occasional dangers of this therapy are fully stated.

The whole book provides an admirable summary of all the important recent work on this subject, and is enriched by two coloured plates and numerous diagrams.

#### "RECENT ADVANCES IN ANATOMY"

THE character of the contents of *Recent Advances in Anatomy*,<sup>1</sup> by Professor H. WOOLLARD, now of Adelaide, is rather unexpected, for it deals, as will be seen, mainly though not quite exclusively with microscopical structure, the preface, indeed, confesses that many aspects of anatomy—such as the racial and constitutional, anthropological, large veins of comparative anatomy, and much embryology—are either omitted or mentioned only incidentally. Much that is usually taught in physiological courses is set forth clearly and attractively in this well written volume—for example, the chapter on oestrus, ovulation and menstruation, the account of the origin of the blood cells, and the description of the cerebrospinal fluid. The first chapter, entitled "microdissection," deals with the instruments employed in the dissection of individual cells and then with mitochondria, the recently discussed Golgi apparatus, and the chromosomes. This chapter, like all the others, has a short but useful list of references for the reader who desires to follow the subject to its original sources. The second chapter is devoted to a description of tissue culture, and in another the morpho-

genesis of nerve fibres is considered. In the chapter on "growth centres and organizers" some of the problems recently investigated by experimental embryology, especially in connexion with the eye, are set out and illustrated by pictures taken from Spemann's paper.

The reticulo endothelial, or, as it is preferably called, the macrophage, system is fully described, its characteristic movements—vital staining, phagocytosis, and amoeboid movement—but its functions are admitted to be constantly expanding. The anatomy of the extrapyramidal system is given in some detail, with an account of S. A. K. Wilson's work on the fibre connections of the corpus striatum and Elliot Smith's researches into the comparative anatomy. The symptoms of extrapyramidal disease are summed up as muscular rigidity unaccompanied by any change in reflexes or in sensation, and involuntary movement ranging from tremor to athetosis. In the chapter on proprioception and epicritic sensation the subject, as represented by Sir Henry Head's opinions in 1920, is reviewed in the light of the more recent publications of Professor Stoppford, Dr E. D. Adrian, and Sir John Purdon.

The last chapter deals with x-ray anatomy, and the points out the number of bony variations which may mutate features. The association of hypothyroidism with pseud-epiphyses, atypical epiphyses, and accessory nasal elements is cautiously discussed. Reference is made to the light thrown by radiology on the position of the normal stomach, and the existence of two forms of stomach—the hypersthenic or highly placed and the asthenic or very low stomach—depending on bodily constitution. This constitutional influence holds sway as regards the other abdominal contents, and the same types of position have recently been shown to exist in the gall bladder by L. Davis of University College, London.

#### TEXTBOOKS OF MATERIA MEDICA

NEW editions of two very well known textbooks of materia medica have just appeared. These are the nineteenth edition of HALE-WHITE's book<sup>2</sup> and the thirtieth edition of that by BATE and DILLING.<sup>3</sup> So many generations of medical students have been familiar with these volumes that it is unnecessary to say anything regarding their general scope and quality. In point of seniority Bate and Dilling has the advantage, since it first appeared in 1884, and the first edition of Hale-White appeared eight years later. In the case of both books the new editions include numerous important new drugs. Sir William Hale-White has introduced sarsaparilla and the lead treatment of cancer, in both cases, however, he has adopted the policy of a cautious reserve in describing the results obtained with these drugs. In the case of protein therapy he has given a favourable verdict for its use in hay fever, but has been less certain of its value in asthma.

It is six years since the previous edition of Bate and Dilling appeared, and hence the present volume contains a long list of new drugs, of which insulin is the chief. Novarsol, sarsaparilla, Bayer 205, typharamide, and mercuriochrome are the chief new synthetic drugs included. Some other new uses or new drugs not mentioned in the morrhuaes in tuberculosis, carbon tetrachloride in ankylomiasis, and the chaulmoogates in leprosy and in mykylomiasis, acetylene and propylene in anaesthesia, butyn and borocaine in local anaesthesia, malarial therapy in neurosyphilis, scarlet fever antitoxin, protein therapy, and ultra-violet light treatment. This list of new drugs shows how thoroughly the volume has been brought up to date, and it also indicates how important are the advances that have been made in recent years in therapeutics. Moreover, the subjects in the list indicate the remarkable variety of the forms of therapeutics that have been introduced in recent years.

As has been already stated, both books are so well known that it is superfluous to proclaim their general merit, but enough has been said to indicate that the new editions have been brought completely up to date.

<sup>1</sup> *Materia Medica, Pharmacology and Therapeutics*, by H. Woollard, M.D., London, 1927. (Fcap 8vo, pp. vii + 712, 10s. 6d.)  
<sup>2</sup> *Materia Medica and Therapeutics*, by W. J. Bate and W. J. Dilling, M.D. (Hon.) and M.D. (Hon.), F.R.C.P., and W. J. Dilling, M.B. Ch.B. (Hon.) Third edition, revised, London, 1925. (Fcap 8vo, pp. x + 652, 6s. 6d.)

<sup>1</sup> *Recent Advances in Anatomy*, by H. Woollard, M.D., London, 1927. (Fcap 8vo, pp. vii + 712, 10s. 6d.)

## BIOLOGICAL CONSTANTS

The first volume of *Tabulae Biologicae*,<sup>1</sup> edited, with the assistance of ninety contributors by C. OPPENHEIMER and L. PRINGSHEIM, was published about two years ago, and, together with the second, was reviewed last year (1926, vol. 1, p. 832). The fourth and last volume, which has just appeared, contains a mass of information concerning inheritance and variation.

The first 115 pages are devoted to the enumeration of the chromosomes in the different species of plants and animals. This is followed by a review of the chief known examples of Mendelian inheritance, it includes a summary of the known examples of the inheritance of diseases and malformation in man. The volume concludes with an index to the whole work. This index, which occupies 200 pages, is, of course, one of the most important features of a work of reference of this nature. It has been carefully prepared, the key words are given in German, English, and French, whilst the names of species are cross-indexed under Latin and German.

*Tabulae Biologicae* will be found to be of very great value by all workers in biological sciences for it provides an easy method of finding out the chief information that is available on any subject. Its special merit is that it covers all the biological sciences. Many important biological problems are of interest to several branches of science and this work makes it possible to find out what has been done on a given problem, not merely by workers in one science, but by all workers in biological science. The information in it cannot, of course, compare in its accuracy with the physico-chemical constants collected in such a work as that of Landolt-Bornstein, but this is not the fault of the compilers and the collection of this mass of material ought to encourage the determination of biological constants with greater accuracy.

The book is fairly dear, for the volumes are not sold separately and the set costs £12 10s. unbound. Since, however, the volumes consist almost entirely of tabulated matter, their preparation must of necessity have been very expensive. Moreover, it must be remembered that the publishers offered the set at the very cheap price of £5 to those who had sufficient confidence to subscribe to the work in advance.

## NOTES ON BOOKS

The work on *Preventive Pediatrics*<sup>2</sup> by Dr. BORDEN S. VEEDER, professor of clinical pediatrics at the Washington University School of Medicine, forms the fourth volume of the system of clinical pediatrics edited by Dr. Royal S. Orrs Haynes. The book is divided into three sections devoted respectively to the growth and development of the child, including chapters on physical and mental growth, nutrition and diet, hygiene and education, the prevention of disease with consideration of the morbidity and mortality in infancy and childhood, and methods which include pre-natal clinics, infant welfare, the care of pre-school children, and school hygiene. An appendix contains specimens of weight charts, record forms, and a bibliography.

When Sir Jonathan Hutchinson suggested, or reintroduced, to parents the plan of recording in a book their infants' progress, he probably did not foresee the literary and artistic refinements to which the plan might lead. In *The Little One's Log*<sup>3</sup> Lady ERLING has compiled a handsome volume with charming illustrations by Mr. E. H. Shepard. The foreword by Dr. ERIC PRITCHARD is adorned by the inevitable stork which drops an infant lying crouched in a kind of inverted uterus down a chimney pot. The book is arranged with alternate pages of letterpress and record. The information in the letterpress seems sound and the record makes provision for such minutiae as Baby's First Curl. A bibliography of books on the care of the child, and suggestions to the child's library completes the volume. If mothers find the time to keep these records doubtless they will as Dr. Pritchard says meet with their reward.

*Tabulae Biologicae*. Edited by C. Oppenheimer and L. Pringsheim. 100 contributors. In four volumes. Vol. IV. P. 115. W. Junk 1927. (Sup. for 8vo pp. vi + 237 7 maps. £12 10s. the four volumes. 10s. 1s. 6d. separately.)  
<sup>1</sup> *Preventive Pediatrics*. By Borden S. Veeder, M.D., New York, and London. D. Appleton and Co. 1926. (Roy. 8vo pp. x + 235 figures 16s.)  
<sup>2</sup> *The Little One's Log*. By Lady Erleigh. With foreword by Dr. Eric Pritchard. London: W. & W. Partridge and Co. 1927. (Crown 8vo pp. 50 illustrated. 6s. net.)

## PREPARATIONS AND APPLIANCES

## A Ligature Applicator for Tonsillar and Other Deeply Seated Vessels

SM. JAMES DUNDAS GRANT, K.B.E., M.D., F.R.C.S., sends the following description of an apparatus to facilitate the ligature of tonsillar and other deeply seated vessels. It consists essentially, he writes, of a glass or metal tube of about four inches in length and a metal carrier, somewhat longer, with a notch at one end. The ligature preferably of catgut (not long soaked), is doubled and pushed through the tube by means of this carrier (Fig. 1). The projecting loop of the ligature is then secured by means of a pledget of gauze and the wire guide removed.

One loose end of the ligature is then marked by means of ink or a knot in order to distinguish it. A half knot is then made in the other loose end and the marked one pushed through it. The half knot is then tightened (Fig. 2). We thus have a sliding knot round the marked end. The ligature loop (which may be considerably longer than is shown in the illustration) is passed over the forceps with which the bleeding vessel has been clipped and is pushed down by means of the tube till it encircles the vessel. If the marked external end is then pulled, the loop on it will pass down the tube and grip the vessel (Fig. 3). The carrier and tubes have been made for me by A. Charles King, Limited, 34, Devonshire Street, W.1.

## ROYAL MEDICAL BENEVOLENT FUND

At the last meeting of the case committee fifty cases were considered and £648 was voted to forty four applicants. Below is a summary of some of the cases relieved.

Widow, aged 67, of M.D. who died in 1921. Her only income is 10s. a week in respect of a son killed in the war. The responsibility of the home falls on a son aged 35 but at the present time he is only earning £2 a week after being out of work for some time. Applicant has had many money losses and she has to keep her daughter at home to look after herself and the cottage (rent of cottage 10s. a week). Voted £24 in quarterly instalment.

Daughter, aged 22, of M.R.C.S. who died in 1907. On the death of her father she took a boarding house which she was obliged to give up in 1925 owing to ill health. In June this year she took another house but unfurnished room, retaining two for herself to carry on a sewing business. Voted £25 to meet rates and to buy some furniture for her room.

Widow of L.R.C.P. who died in 1925. She tries to support herself by envelope address which rarely brings in more than 10s. a week. Total help given £20 and £25 voted in quarterly instalment. This grant is supplemented by the Royal Medical Benevolent Fund Guild which gives 10s. a week.

Widow, aged 59, of L.R.C.P. who died in 1904. Her only income is rent from a house which amounts to 15s. after deducting expenses for repairs. Rent including fire and light £43 per annum. A 1s. for renewal of grant as her income is insufficient to meet her expenses and increased rent. Previous help £10. Voted £10 in two six monthly instalments.

Daughter, aged 64, of M.P.C.S. who died in 1920. Up to 1922 supported herself as a laundress but owing to ill health had to give up work. Income from investments amounts to £50 per annum. Relations give £4. Applicant does not pay any rent but £5 for rates. Voted £15 in four quarterly instalments.

Subscriptions may be sent to the Honorary Treasurer, S.R. Charters, Symonds, at 11 Chandos Street, Cavendish Square, London W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing especially for coats and suits for ladies and girls holding secretarial posts and suits for working boys. The Guild appeals for second hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street W.1.

## LARYNGECTOMY FOR CANCER OF THE LARYNX

SEMON LECTURE BY MR LIONEL COLLEDGE

THE Semon Lecture, under the auspices of the University of London, was delivered in the Barnes Hall of the Royal Society of Medicine on November 3rd by Mr LIONEL COLLEDGE, surgeon to the Ear and Throat Department of St George's Hospital, who took for his subject "The present position of laryngectomy for cancer of the larynx."

Mr Colledge said that laryngectomy had been applied to cases of extrinsic cancer of the larynx, really pharyngeal cancer—that is, to cases in which the growth had originated on the aryepiglottic folds or epiglottis—or combined with partial excision of the pharynx to the post-epiglottic carcinoma of women, and to growths arising in the fossa pyriformis.

For the first class of case—growths of the aryepiglottic folds and epiglottis—if an operation was advisable a pharyngotomy was generally more suitable, for such tumours were situated in the pharynx, and the principle so persistently advocated by Mr Trotter of adequate exposure and removal of the growth rather than of any particular organ must be followed. In the second class—post-epiglottic carcinoma in women—it was not necessarily imperative to sweep away the front of the neck, including the larynx, in order to excise the epithelioma. In the case of a lady, aged 38, after resection of the lower part of the pharynx and upper end of the oesophagus, the resulting defect was replaced by a flap of skin. The larynx remained intact and the open gutter was re-formed into a gullet by a plastic operation. In the third class—tumours of the pyriform fossa—no other operation than laryngectomy was feasible, and a portion of the pharynx, usually a complete segment, must be sacrificed at the same time. This operation of Gluck left the patient in such a condition that a plastic operation must be devised afterwards to re-form the anterior wall of the pharynx.

The performance of laryngectomy upon such cases brought disaster on the operation, and induced Brison Delavan to state some seventeen years ago that up to that time total laryngectomy had added nothing to the sum total of human life. Statistics and case reports showed that no sufficient distinction was drawn between cases of excision limited to the larynx and those in which it had been combined with a partial excision of the pharynx. For example, in the first case of laryngectomy for cancer, reported by Billroth in 1873, the removal included part of the upper two tracheal rings, the epiglottis, thyroid, and arytenoid cartilages, and the lower third of the epiglottis, while in a subsequent case, in a woman of 43, in addition to the entire larynx, the thyroid gland and part of the pharynx and oesophagus were removed. In Langenbeck's first case the hyoid bone and parts of the tongue, pharynx, and oesophagus were removed with the larynx.

A collection of such cases must inevitably be associated with a heavy operation mortality, but in spite of this the following analysis by Crile of cases reported between 1873, the date of Billroth's first operation, and 1901 tended to show a steadily diminishing death rate.

1873 to 1876	12 laryngectomies	1 ultimate cure = 8.33%
1876 to 1886	108 "	21 " " = 19.44%
1886 to 1896	156 "	49 " " = 23.82%
1896 to 1901	30 "	20 " " = 66.67%

Sendzick (*Die bösartige Geschwulste des Kehlkopfes*) gave a similar record of progress.

Recent reports concerning almost entirely cases of intrinsic cancer too advanced for excision of the growth by laryngofissure were far more encouraging, and indicated that in well selected cases, if the operation was performed in suitable circumstances by a surgeon who had made a special study of the technique and subsequent management of the case, the risk was now quite small. For example, Lipka (Madrid) had reported 107 cases with 5 deaths due to the operation, a mortality of less than 5 per cent. Moore and Portmann (Bordeaux) and Mackenty (New York) had each reported a series of 31 laryngectomies without a death, and Mackenty had later reported 102 laryngectomies with 4 deaths, all these four patients being diabetics. Crile had recorded 27 cases with 2 deaths and various

other short series similarly successful had been reported during the last ten years. The most striking figures were those of Gluck, who reported as long ago as 1894 that 23 out of 26 consecutive patients recovered, while in 1914 the total number of his simple laryngectomies amounted to 172, including a series of 72 cases without a death. Soerensen had recently reported the vast total of 700 laryngectomies from this clinic.

Allowing for the tendency towards optimism inseparable from large collections of surgical statistics, it might fairly be assumed that the mortality of the operation would be as low as 5 per cent under the favourable conditions already mentioned, and it was hardly likely to fall much below this figure for so severe an operation. The occasional operator who had not made a special study of this type of operation was likely to be faced with a much higher death rate, and Hajek still considered that the mortality was really in the neighbourhood of 50 per cent. At the present time the operation was almost limited to cases of intrinsic cancer too advanced for any conservative operation—namely, laryngofissure or partial excision. In such cases the pharynx was not invaded, and only such a small part of it had to be removed as was necessary anatomically to enter the larynx, its closure presented no serious difficulty, and there was usually no need for any plastic operation or the use of skin flaps. Many lasting cures in such cases could be claimed.

Such cases of advanced intrinsic cancer included the following types:

(a) Where the disease had extended at all widely into the subglottic region. There was a high percentage of recurrence after laryngofissure in this condition, owing to the difficulty of elevating the mucous membrane below the lower edge of the thyroid cartilage, and the case with which the disease spread through the cricothyroid membrane and crossed the middle line.

(b) Where the disease crossed the anterior commissure and invaded both vocal cords.

(c) Where one or both vocal cords were fixed and there was extension to the arytenoid region. Although fixation of one cord did not necessarily contraindicate laryngofissure yet such cases showed a large percentage of failure, and the question whether this operation or a partial or total excision of the larynx was the appropriate operation must be considered in each individual case. Even laryngectomy, or some modification of it, would result in a better voice and less social disability, but in many cases a permanent tracheotomy was necessary afterwards in spite of the attempt to preserve an airway through the larynx, and there was a greater risk of recurrence.

(d) Where both vocal cords, the ventricular bands, and the subglottic region were attacked and the larynx was choked with growth, no doubt could arise that laryngectomy was the proper operation.

(e) Where the disease had recurred after laryngofissure, though occasionally a second fissure or partial excision might succeed, laryngectomy was generally a more suitable operation and should be preferred to a lesser operation. Mr Colledge had performed the operation seven times on patients who had previously undergone laryngofissure. Of these, four died within a year from another recurrence, one died from heart disease clinically free from any trace of cancer, and two only remained well six years and three years respectively after the laryngectomy. Recurrence after a laryngofissure, therefore, was not so hopeless as had been thought, but the outlook was clearly not so encouraging.

Besides the selection of cases there were certain other considerations, of which the recognition nowdays is influenced the results of operation beneficially.

The decision whether laryngofissure, laryngectomy, or some intermediate procedure was the appropriate operation for the case was of the utmost importance. This decision should be made before any operation was begun and it was left to an exploratory investigation, because laryngofissure preceded by thyrotomy was a longer and more complicated operation than a deliberately planned laryngectomy. If any doubt existed it would generally be found that laryngectomy was required, but each surgeon could be guided by his own views and experience—one inclined to

larynx wherever possible, another determined to place the risk of recurrence beyond every other consideration.

Recurrence after thyrotomy should be extremely uncommon, but no larynx should be sacrificed unnecessarily. On the other hand, the surgeon should not allow himself to be forced into operating on an unsuitable case on the plea that the disease was inevitably fatal.

The general condition of the patient was of the utmost importance, and might be a contraindication in a case otherwise suitable for operation. In this connexion it must be remembered that in elderly people the growth might be present for a long time before ultimately destroying life. In a case observed by Mr Colledge the patient who declined any form of operation whatever, survived four years from the time that the growth was first recognized. The most remarkable case was that of Gleitsman, which had been ultimately recorded by Harmon Smith. A man, aged 53, came under observation with cancer of the larynx, proved histologically, the larynx was successfully removed thirteen years later by Dr Brewer.

Age in itself was no contraindication. A medical practitioner aged 73, passed through the convalescence without any complication or even rise of temperature, and returned to carry on his practice until his death some months later from an unexpected recurrence of the disease at the root of the neck. Generally, however, it was natural that the younger the patient the better was the operation supported. Three of Mr Colledge's patients between the ages of 40 and 50 caused very little anxiety. Those of spare build with long thin necks were better subjects than fat people with short thick necks, and those addicted to tobacco and especially alcohol, were invariably in a poorer position to withstand any severe operation but particularly a laryngectomy.

Prolonged dyspnoea appeared to exercise a pernicious effect on the general nutrition and to cause wasting. Such patients withstood the effects of the operation very badly. A thin wasted man of 56, who had increasing dyspnoea, which would soon have rendered a tracheotomy essential to life, succumbed to sloughing and septicaemia in a week, although he was edentulous and in other respects a suitable subject.

In the operations of pharyngotomy and laryngectomy the wound in the neck was in direct communication with the mouth, and in overcoming sepsis the surgeon was presented with a problem entirely different from that in laryngofissure, in which it was comparatively simple to maintain an aseptic technique. Saliva, reaching any raw surface produced a slough, so that if any leakage occurred healing by first intention was impossible and could only take place by granulation after the sloughs had separated. The presence of infective material in the secretions of the mouth in these circumstances constituted a serious risk, and should in operation be undertaken without removing every septic tooth the wound would certainly be attacked by a severe streptococcal infection, and the patient might rapidly succumb to septicaemia or broncho-pneumonia. The state of the tonsils and accessory sinuses might play some part and their condition should certainly be investigated, but it was the teeth which were all important. The patients frequently had reached an age at which they were either already edentulous or infection of the gums and tooth socket had begun.

The most satisfactory cases were those in which the teeth had been removed and two to three weeks allowed to elapse while the gums healed. The immunity seemed then to have reached its highest point and it was possible to obtain healing by first intention. It was most important to allow a sufficient interval between the extraction of the teeth and the operation. The edentulous also were favourable subjects, but in course of time the immunity to mouth infections seemed to become lower. Patients with really good teeth and gums—an exceptional condition—did well, but there was always some sloughing. Patients with bad teeth and pyorrhoea should not undergo operation until they had been converted into Class I.

A preliminary tracheotomy must generally be avoided but it might be necessary if the patient was exhausted by dyspnoea, not infrequently it had been previously performed and sometimes in the high position immediately

below the second. A preliminary tracheotomy or a palliative tracheotomy should be as low as possible. If a low tracheotomy had been performed the larynx could be amputated from the trachea above the tracheotomy opening and the cannula left in position during healing.

Apart from tracheotomy, if the growth extended low down it might be necessary to remove a few rings of the trachea with the larynx to give an adequate margin below. If there had been no preliminary tracheotomy and the growth caused respiratory obstruction during the operation a laryngotomy tube introduced through the cricothyroid membrane would give relief. This was Botet's advice.

Mr Colledge thought that the epiglottis should always be removed. It became useless and might cause difficulty in swallowing later on, but what was more important it might be the site of a recurrence. In no other operation was the subsequent care of the patient of greater importance.

The objections raised in connexion with the ultimate results of the operation concerned social, physical, and mental disabilities. It had been stated that speech was impaired or reduced to a whisper, that the neck was disfigured, and that there might be a predisposition to pulmonary disorders or even to the aspiration of foreign bodies into the air passages. Initially the mental depression had been said to lead even to suicide. Actually most patients developed a useful pharyngeal whisper, and occasionally the pharyngeal voice might be of such a quality that there was no disability. Professor Burger, in 1925, had demonstrated such a patient, who was able to make himself heard all over the Barnes Hall, and Professor Burger described his researches on the manner in which this voice was produced. In another patient, on whom Sir Robert Woods had operated eight years previously, the voice except for a slightly croaking quality, was perfectly natural, with a slight Irish accent the patient produced it without difficulty or apparent effort in the vibrations of two bands, which seemed to correspond to the upper edges of the middle constrictor.

Less fortunate patients were either satisfied with a whispered voice or could employ some form of phonatory apparatus. Patients did not take very readily to the use of an artificial larynx but one had combined certain parts of the Trapa apparatus with other parts of the Mackintosh-Western apparatus into an artificial larynx, which really suited him. With this he was able to carry on a very active professional life as the leading partner in a firm of architects.

There was no direct evidence that these patients were especially liable to pulmonary disorders, though Professor Moore had noted that out of thirteen patients who remained free from recurrence four succumbed later to broncho-pneumonia. These patients were usually remarkably free from coriza, due probably to the abolition of nasal respiration. The entry of foreign bodies into the trachea did not seem to have occurred. The disfigurement of the neck was but slight, and the permanent tracheotomy was part of the price paid for the cure of the disease, which unchecked, would eventually necessitate this operation in almost every case. It might be claimed, therefore, that if the patient was willing to undergo the operation, his ultimate condition was no worse than that of one suffering from any form of permanent and complete laryngeal stenosis and the voice occasionally might be much better. The depressing effect on the mental state had been exaggerated; the patients were usually cheerful and active, and Mr Colledge had not encountered the despair and melancholia leading to suicide described by some writers.

In a general way it might be concluded that the operation in properly selected cases was justified by its results, both immediate and remote and that it was too often declined. When an operation was feasible Mr Colledge did not think that there was a satisfactory alternative as a routine treatment. The use of lead and x rays had been disappointing. Radium was very apt to lead to necrosis of the laryngeal cartilages without eliminating the growth but recently Mr Harner had reported improved results by employing small doses in needles over prolonged periods after resecting the thyroid cartilage to fashion a window

In the first of these cases the result after three years had been much superior to a laryngectomy, leaving the man with a normal larynx, movable cords, and a good voice. Nevertheless, Dr Thomas J Harris had written in the present year, from a large experience of radium in laryngeal cancer: "Certainly if I had cancer and the condition was too far advanced for an operation I would prefer to endure the disease rather than to risk the uncertain results of radium treatment."

There would always be those who preferred to try radium, for the operation sometimes failed and radium might succeed.

## THE STRANGWAYS COLLECTION

### PATHOLOGY OF RHEUMATOID JOINTS

Of additions made to the museum of the Royal College of Surgeons of England in recent years none is more worthy of record than that known as the "Strangeways Collection"—the preparations and specimens assembled by the late Dr T S P Strangeways during the years he devoted to the study of those human ailments which are accompanied by chronic and often painful changes in joints. The collection contains about 800 dissections and preparations with some 3,000 microscopic sections, all of which bear upon the pathology of joints undergoing changes of a rheumatic or rheumatoid nature. The circumstances in which Strangeways built up this collection were altogether of a peculiar kind, and deserve more than a passing notice.

Strangeways died on December 3rd, 1926, on the eve of completing his sixtieth year. Fame came to him late in life. During his last six years he made the Research Hospital of Cambridge the leading institution in this country for the study of living tissues cultivated and grown in artificial media. He drew round him a trained and enthusiastic band of workers, who now successfully strive towards the goal he had hoped to reach. At first sight it may seem that there can be no connexion between an inquiry into the artificial changes of chronic rheumatism and a study of living tissues grown in artificial media, yet in Dr Strangeways's case the one inquiry led on to the other in the most natural way.

Strangeways entered as a student at St Bartholomew's Hospital in 1890, and in 1896, when 30 years of age, became a member of the Royal College of Surgeons. At his hospital he was brought, as were many others, under the influence of the late Professor Kantack, who was appointed to the chair of pathology in Cambridge in 1897. Strangeways followed him there, becoming his demonstrator, a choice determined not only by an inclination for laboratory work in preference to practice but also by a partial but increasing degree of deafness. In 1905, when he was made Huddersfield lecturer on pathology in Cambridge under the late Professor Sims Woodhead, he began to strike out on his own path in life. Coming to the conclusion that a pathologist could make headway only when he studied disease in the living as well as in the dead, he set about putting this idea into execution. He found that his friends Sir William Osler, Sir Clifford Allbutt, and Professor Sims Woodhead were willing to help him and "cover" him, they became a "Committee for the Study of Special Diseases"—the particular diseases chosen for study being those which were accompanied by slow deforming changes in joints—chronic rheumatic arthritis in its numerous forms and degrees. Some £480 were raised by subscription, a house was taken, three beds were purchased and filled, a matron and nurse engaged, an x-ray apparatus installed, and the coal shed in the garden converted into a laboratory and museum. In 1906 another bed was added, and Dr G W Nicholson was appointed research scholar and began his fruitful inquiries into those microscopic changes in bone and cartilage which mark the successive stages of chronic osteoarthritis. Literature was unsparingly searched for the best knowledge bearing on chronic rheumatic disorders, beds were added, the Poor Law infirmaries in London were tapped for material, a research scholar in chemical pathology was appointed and another in bacteriology, and Dr Strangeways giving his services voluntarily and shouldering the chief burden of obtaining financial support. In 1907 the

hospital cost £256 to run, records of a thousand cases were accumulated and analysed, hundreds of specimens were dissected and examined, the most interesting being served as the nucleus of a museum. In 1908 funds were exhausted, but, nothing daunted, he appealed for a large scheme—a special research hospital. He asked for £350 and obtained £846. His museum was becoming large, his records very numerous, and his family responsibilities were also growing, but these he blithely shouldered with his other liabilities. He had become convinced that arthritic deformations covered a multitude of disorders which had to be disentangled before any attempt could be made to relieve suffering by scientific means.

Sir Otto Beit, Sir Robert Brown, the Medical Research Council, and other friends came to his aid, and by 1912 £4,000 had been raised and a special research hospital built in Hills Road, a mile and a half from Cambridge. The executors of Sir William Osler came to the funeral and of this voluntary worker. Thus it came about that in August, 1914, when the war broke out there was a hospital in Hills Road with beds for twenty-one patients, a well equipped laboratory, and a museum. By then full records of 4,000 cases of chronic arthritis had been accumulated and studied, 2,000 joints had been minutely examined, over 3,000 microscopic sections had been cut and studied, and over 800 preparations arranged on the shelves of the museum. Soon after the outbreak of hostilities the Hills Road Hospital was taken over by the military authorities. Strangeways, in the intervals of military service found time to prepare a typewritten account of the investigations he had made into the nature of osteoarthritis and allied disorders. In 1917 the hospital reverted to its original purpose and Mr Strangeways resumed his investigations. In 1918 he published in account of the microscopic changes in joints affected by chronic changes, and another paper in 1920 on the nourishment and growth of loose bodies in joints, a paper of great importance because from the experience therein related, he passed, in a most natural way, into an altogether new field of inquiry. He found that the synovial fluid within a living joint was a medium in which particles of cartilage could grow and that he had thus at his disposal an excellent method of studying the growth and nourishment of cartilage. From the growth of cartilage in the synovial fluid of joints it was an easy and natural transition to the cultivation of living tissues in artificial media. And thus it came about that a hospital established for the study of a special disease became launched as a progressive and fully equipped laboratory for the microscopic study of living tissues. To-day the work begun under Strangeways is being continued under Dr J A Andrews.

After Strangeways's death those who were responsible for the upkeep of his collection of specimens had to determine how it could be utilized to the best advantage. The collection, with all documents relating to it, was offered to, and accepted by, the council of the Royal College of Surgeons of England. The council invited Mr R L Knaggs, F.R.C.S., to make a critical examination of all the specimens and to compile a descriptive catalogue of the collection. The choice of Mr Knaggs was particularly happy, for the chapters he devoted to arthritic deformations in his work *Diseases of Bone* mark him out as an authority in all that relates to the pathology of osteoarthritis and rheumatoid arthritis. The task he has undertaken is not an easy one. Most of the specimens which require redissection and remounting, their histories have to be searched for in Strangeways's notes and writings. It is mainly there will emerge a series of specimens which will do justice to Strangeways's memory. It will be remembered that Strangeways recognized six types of arthritic deformations, and all the specimens which he had marked as representative of his various types will be carefully preserved but an examination of the type specimens shows that the criteria on which his classification was based are clinical rather than pathological. The more specimens will be preserved as a separate collection and will be available for the use of all research students.

## CHRONIC SEPSIS AND THE PSYCHOSES

IN this year of the centenary of the birth of Lister, who by his brilliant post-operative sepsis made surgery safe for mankind Sir Berkeley Moynihan, President of the Royal College of Surgeons of England with the sympathy natural to a physician doomed to the practice of surgery has more than once drawn attention in eloquent terms to the notable advance made by the recognition of the existence and importance of medical sepsis. In so doing he has paid a well deserved tribute to the services of Dr William Hunter in applying Lister's teaching to general medicine, describing him as having been for years a voice crying in the wilderness. A like fate has attended many other pioneers and it is always hard to foretell the bearing of a piece of research and to prophesy what far reaching effects may eventually result from work undertaken solely to arrive at truth or directed to the solution of some special problem. After working at Leipzig on intraperitoneal transfusion of blood and the fate of the absorbed blood the distinguished Edinburgh graduate Dr William Hunter was elected John Luer's Walker student at Cambridge in 1887 he spent the three years of his tenure in beginning the investigation of the pathology and etiology of pernicious anaemia, and soon came to the conclusion that the haemolysis was due to the action of toxins absorbed from the alimentary canal. With rare persistence he followed this trail and pointing out the sore tongue, oral sepsis and streptococcal gastritis he arrived in 1900 at the conception of what has now become a commonplace—the influence of local infection on the body generally. In America the writings of Frank Billings of Chicago on focal infection followed these clear expositions of oral sepsis. The new term though describing the same process has a wider connotation and it is now recognized that the original focus may arise in various parts of the body, in the Fallopian tubes or prostate among others, and that when it starts in connexion with the teeth it may establish a secondary focus elsewhere—in the tonsils, gall bladder, appendix, intestine or even a joint—before the original focus is eliminated by the establishment in this way of another active centre for bacterial activity. The diagnostic connexion may be obscured and remedial treatment rendered difficult and disappointing. The influence of focal sepsis has been accepted in connexion with the etiology of acute rheumatism and while altering our conception of that disease bids fair, through the removal of the faucial and pharyngeal tonsils and other foci to combat the heavy toll of crippling cardiac rheumatism. But even so, and perhaps because of the inherent difficulties medical anti-sepsis and sepsis have it must be admitted lagged much behind the example set by surgery.

As Dr William Hunter points out in the paper (published at page 811) on chronic sepsis as a cause of mental disorder with which he opened the discussion in the Section of Mental Diseases at the Annual Meeting at Edinburgh there are differences between what is ordinarily understood as medical and as surgical sepsis. Medical sepsis is usually chronic and of a

more complex character the foci are often small hidden, and not infrequently latent as regards symptoms. Experience is epigrammatically designated by Sir Berkeley Moynihan as the name we give to our mistakes, and experience in hunting for these foci in cases of chronic arthritis or neuritis often proves that they are far from easy to locate. The interesting observations of Rosenow on the special selective action of certain strains of streptococci are quoted but here as was pointed out in Sir Berkeley Moynihan's contribution to the discussion in his paper on The relation of aberrant mental states to organic disease (p. 815) the qualities of the soil as well as those of the seed must be taken into account. It is indeed, common to see persons with advanced oral sepsis with little or nothing in the way of secondary results, such as arthritis, fibrositis and neuritis and as already mentioned to see on the other hand patients with these disabilities in whom an infective focus is far to seek. The results of medical sepsis are now fully recognized as numerous and wide-spread among them modifications of the endocrine balance and of the closely associated activities of the nervous system open up vistas presenting many problems full of interest and tempting speculation.

It is particularly fitting that at Edinburgh so closely associated with Lister there should have been in this Lister's year a discussion on the subject mentioned, and that it should have been opened by Dr William Hunter—a graduate of the Northern Athens. Psychiatrists have not been backward in showing how great may be the influence of chronic infection in the production of mental disturbance as is illustrated by the references to the remarkable experiences and results reported by Dr H. A. Cotton of the New Jersey State Hospital Trenton where the number of discharges increased from 37 to 85 per cent after the removal of oral and tonsillar infective foci. This subject was also raised in the discussion on the prophylaxis of mental disorder in the Section of Neurology and Psychological Medicine at the Bath meeting of the Association two years ago by among others Dr P. Watson Williams, who forty years before had recognized the importance of the toxic factor but stated that in the larger proportion of cases of mental aberration the determining cause was not infection thus agreeing with the wise warning of Professor Adolf Meyer of the Johns Hopkins University (quoted with approval by Dr Hunter) not to regard all insanity as due to infection. Dr Chalmers Watson during the discussion ascribed disseminated sclerosis and many acute and chronic mental disorders to septic foci and spoke highly of the value of colonic lavage and Plombiers douches. The experience of two superintendents of large mental hospitals provided cause for critical consideration of the opener's thesis. Dr D. K. Henderson doubted the deductions drawn as to the dependence of psychoses on sepsis and Dr W. T. Menzies pointed out that the hypothesis of the septic factor in insanity was forty years old, that chronic sepsis was not more frequent in the insane than in the sane and that the recovery rate had not been materially raised by antiseptic measures.

As he considers the incidence of chronic sepsis among the insane of this country to be much higher than in any other group of hospital patients, Dr William Hunter pleads for early removal of any septic focus so as to prevent permanent and irreparable damage and that in order to achieve this new era of anti-sepsis in mental disorders and the cure of 'septic psychoses'—a term approved by Dr W. A. Potts—

each mental hospital should be as fully equipped for surgical and specialist work as it has hitherto been for medical and nursing care. Though obviously right in principle, this counsel of perfection must encounter financial difficulties which, in the present position of affairs, have to be taken into account, perhaps, however, these may be overcome by some arrangement with neighbouring hospitals, so that a system of team work not unduly costly can be successfully brought about. In the meanwhile, as recorded in our issue of October 22nd, a move in the right direction has been made at the new reception hospital for mental patients at Northampton.

### THE WORLD POPULATION CONFERENCE

For several days this autumn a large number of persons, including a fair proportion of scientific men of established reputation, were gathered together at Geneva to engage, in the words of the president, Sir Bernard Mallet, in "a full discussion on purely scientific lines of the theories, facts, and statistics relating to population problems." The *Journal* of the Conference, which is the only record of its proceedings at present available, is necessarily too concise to permit us to appraise the value of the papers read. Thus we should no doubt be wrong in concluding, as the summary tempts us to do, that M. Albert Thomas, save for a proposal to create one more permanent international organization, dealt exclusively in vague eloquence. In fact—again judging from the summary—possibly our proviso is superfluous, for the new international centre, we read, "should apply itself indefatigably to acquiring the necessary authority for defining population needs and proposing the means to satisfy them," which sounds a trifle nebulous. Of the scientific contributions in a narrower sense, Professor Pearl's seems to have contained nothing which he has not admirably expounded elsewhere, Mr. E. J. Lindbette's analysis of proper stocks requires more detailed exposition to be really intelligible and convincing, and Professor Cair-Saunders's contribution on differential fertility seems to have been rather slender.

As we have said, it is not fair to judge from so bald a summary, and in any case the *imponderabilia* of an international gathering, the advantage of bringing into contact intellects profoundly different innately and by training, of converting a name into a personality, are not measured by a *process verbal* or even a complete report. It may well be that this conference was a great success, and the report before us at least testifies to the pleasure it gave its participants. At the same time, such a summary does bring into consciousness doubts whether there are not many important topics which cannot be usefully discussed by international gatherings, and whether the business of persuading scientific men to assemble at, say, Geneva is not being overdone. It is obvious that neither the policies of national Governments in the matter of immigration laws nor the practices of individuals in the matter of "birth control" are in the least likely to be influenced by the lectures or resolutions of professors, economists, or any other 'experts'. Sir Bernard Mallet had, of course, no illusions as to this. The sentence we quoted from his opening address shows that he was concerned to secure a strictly scientific discussion of the problems but there seems to be an insuperable difficulty, in that the problems which can be brought under the connotation of population problems are heterogeneous, and, for their comprehension, need a mastery of different

techniques such as the command of one man. A discussion of such measures in general meeting, even when the speakers have a common language, is unlikely to be of much value, it will be of less so to differences of technical knowledge we add differences of language. Many speakers at this conference seemed to think that all would be made plain were some new international bureau created which should "co-ordinate" efforts and "sift the evidence collected." Anybody who has attended international gatherings at Geneva is familiar with this sentiment. The suggestion is that we do not know the answer to certain questions simply because we have not collected enough data. But at least two alternative explanations are possible. The first is that Newtons and Einsteins are rare, the second that we do not know what problems we want to solve. Even permanent residence in Geneva does not convert ordinary men into Newtons, while what is unintelligible in English will still be so when rendered into French.

In our view, not the conference hall, but the study where the papers of other students can be read at leisure, is the proper centre of international co-operation in research into such problems of population as can be solved.

### THE RICKMAN GODLEE LECTURE

LADY GODLEE has founded and endowed at University College a lecture in memory of her late husband, who was a student of the medical school, was appointed assistant surgeon to the hospital in 1877, was Holme Professor of Clinical Surgery from 1892 to 1907, and remained surgeon to the hospital until 1914. He was President of the Society of Clinical Surgery until his death in April, 1925. The foundation is managed by a joint committee of University College and University College Hospital Medical School and the founders desired that the lecturer (who should not be a member of the college or the medical school) should have scope to select his topic from the long list of subjects in which Sir Rickman Godlee was interested. These were enumerated in the trust deed as "medicine, surgery, natural history, natural science and philosophy, history—past and present, political, sociological, art, literature, travel, biography, archaeology, psychology and anthropology." The first lecture was given by Viscount Cecil of Chelwood on October 27th in the Hall of University College to a meeting over which Sir Berkeley Moynihan, President of the Royal College of Surgeons, presided. In a brief introductory speech Sir Berkeley Moynihan said that as the lecturer might deal with any of the subjects in which Sir Rickman Godlee had been engaged, and as his tastes were catholic, and his intellectual faculties almost equal in number to those of the distinguished cousin of the first lecturer, it was legitimate to look forward to a series of most interesting orations. Sir Berkeley recalled his first meeting with Sir Rickman Godlee, by whom he was examined at the Royal College of Surgeons. Godlee had even then greatly distinguished himself as an anatomist, as an artist who had illustrated with unsurpassed accuracy and beauty the gross anatomy of the body, and as a pioneer in surgery. Armed with the weapons which his uncle Lord Lister had forged, he had, with Dr. Hughes Bennett as colleague, operated in 1884 for cerebral tumour. He was soon to publish with Sir James Fowler their work on *Diseases of the Joints*. In the new surgery of the cranial and thoracic cavities Godlee was among the earliest adventurers. How the diverse qualities of physician and surgeon could be caused to work together for the patient's benefit and to the advance of knowledge. In both cases he had laboured in friendly and fruitful co-operation.

physician Godlee, who was President of the Royal College of Surgeons when the speaker joined the Council, was the almost ideal chairman. All business to be considered had been carefully prepared, and every aspect of it most thoroughly studied. He was tolerant of opposing opinions, dispassionate in judgement, prudent in council, wise and circumspect in action. Godlee did not make friends easily. He seemed at first a little aloof, disliking any early approach to intimacies. But he was capable of real affection. Wordsworth said of his wife that her love had ceased to be like a fountain, and had become a well. That was true of Godlee's affection. It did not burst out and immerse one in its revelations, but when sought it was deep and almost inexhaustible. He had a quiet sense of humour and a quizzical enjoyment in intellectual and tactical difficulties. In contrast with Godlee's ignoble things were of no account, and one often left him with a sense of spiritual invigoration and encouragement. Godlee, like Lister, was a Quaker. The selection of Lord Cecil, our champion of peace, as the first lecturer was therefore most appropriate. Viscount Cecil's lecture, which was on

The co-operation of nations, dealt generally with the subject but had special reference to the work of the League of Nations. He laid stress upon the influence to-day exerted by this country in the councils of Europe, and expressed the confident hope that, given only courage and vision, it would be able to take a leading part in saving the world from future wars.

#### THE BRITISH MEDICAL BUREAU

To the great and varied organization it maintains for the convenience and assistance of its members the British Medical Association has this week added a Medical Bureau for giving advice with regard to the transfer of practices as to partnerships and as to assistants and locumtenents and for dealing with other aspects of the business side of general practice. The British Medical Bureau starts with the advantage of commanding the experience of the Scholastic Clerical and Medical Association established in 1880, and already well known to the profession as a trustworthy and successful agency for the transaction of medical scholastic, and accountant business. The arrangement has been brought about as the result of negotiations conducted by the Council with the approval of the Representative Body, whereby a considerable share in the capital of the Scholastic Clerical and Medical Association has been acquired by the British Medical Association, four representative members of which will in future act as directors of this old established company. Details of the work the Bureau will do for members are set out in full in an advertisement printed this week on page 61. As will be seen, the British Medical Bureau will be under the management of Mr. A. V. Storey, who has been long associated with the agency and will also have the services of a staff of qualified accountants wholly engaged on medical work, who will investigate practices, for purchasers and audit books and accounts, and give advice as to income tax. A register is kept of medical men willing to receive resident patients, and the scholastic department will advise as to the selection of educational establishments, private tutors and governesses. From much experience of the work of the Scholastic Clerical, and Medical Association and of its straightforward method of doing business the Association has in the past been able to advise members to consult it and can now commend the new Bureau with every confidence. Members of the British Medical Association will have the advantage of a reduced scale of charges applicable to them. All correspondence should be addressed to Mr. A. V. Storey, General Manager, British Medical Bureau, 12 Stratford Place, Oxford Street, W.1 (telegraphic address: Triform, Wesdo, London, telephone, MAY 1762 and 1783).

#### FIRST AID ON THE ROADS

The number of patients carried by the Home Ambulance Service of the Order of St. John and the British Red Cross Society during the third quarter of the year was 29,107. There are 369 ambulances altogether and the average number of patients carried in each for the three months is 79. The practice of using ambulances for moving patients is increasing five years ago the average number carried during a quarter was only 43. Probably the increase is to some extent due to the greater number of accidents that occur on the roads. Last year in the English counties there were 121,267 accidents in the streets and roads resulting in death or personal injury. A suggestion made a short time ago that a road service should be set up for the purpose of giving first aid to those injured in traffic accidents has been vigorously taken up both by the Order of St. John and the British Red Cross Society. Already the Home Ambulance Service has been instrumental in dealing with an immense number of persons injured in road accidents. A certain number of units of the Order and Society have also for some time past been giving special attention to first aid on the roads. The appeal to extend this work and to place the service on a national basis has met with a very satisfactory response. The work done in this respect during the past summer has been to a large extent experimental, but much useful experience has been gained as to ways in which the service of members of the two societies can be most usefully employed. Depending, as it does, on the service of members of voluntary organizations, the majority of whom are at work all the week, it is principally at week ends and on public holidays that actual roadside work can be performed. It is, however, at those times that the demand is most urgent. In order to meet the needs of those who are injured in road accidents at times when first-aid workers cannot be standing by, a large number of roadside boxes have been erected by local units of the Order and Society. These boxes contain bandages and dressings and in some cases a stretcher is included in the box. If these boxes are not placed where someone is always in attendance to open them, arrangements are made that, by breaking a pane of glass, the key of the box can be obtained. With the growing volume of motor traffic it is, unfortunately, not probable that the number of road accidents will sensibly decrease for some time, and it is hoped that next year the work of giving first aid on the roads will be firmly established as one of the most useful undertakings to which members of the two organizations can devote their skill.

#### THE PREVENTION OF MATERNAL MORTALITY

A MEETING attended by representatives of associations in touch with working women was held in London on October 27th to consider how by the dissemination of information and by administrative measures, maternal mortality might be reduced. The meeting was presided over by Lady Barrett M.D., dean of the London School of Medicine for Women. The chief organizer was Miss Cecile Tuckwell, a member of the Royal Commission on National Health Insurance and the committee in charge of the arrangements included representatives of religious bodies, such as the Mothers Union of the Church of England and the Salvation Army, and industrial bodies, such as the Standing Joint Committee of Industrial Women's Organizations. It was stated that this committee would be kept together to pursue the subject with a view to spreading enlightenment among working women—for instance by the circulation among mothers or prospective mothers of literature containing simple advice on the subject. Sir George Newman, Chief Medical Officer of the Ministry of Health, gave the principal address, in which he said that taking the average of the last ten years 750,000 women in England and Wales gave birth to children each year. In rendering that

service to the nation 3,000 of them died in the act or so soon after that the death was attributed to childbirth, and thousands of others, as evidenced by insurance returns and hospital records, suffered from impairment of health. Of the women who died, 75 per cent were under 35. He sometimes thought that there should be an inquiry into every death from childbirth, for such deaths seemed to him to call for explanation as much as any fatal accident. Three principal measures were urgently necessary. The first was pre-natal hygiene, local authorities had provided between 700 and 800 ante-natal centres, but at present only a small fraction of the 750,000 women just mentioned were receiving effective assistance. It was necessary to create a public opinion which would lead the pregnant woman to consult her doctor in a simple and natural way at the earliest juncture. The second need was for maternity homes. Partly because of the necessity for satisfactory treatment, and partly because of the frequent inadequacy and unsuitability of home accommodation, there were many cases of childbirth in which the woman should be delivered in a maternity home. Since the organization of the Ministry of Health 150 maternity homes, with 2,300 beds, had been established or approved, but further provision on a large scale was still required. The third need was for skilled and competent assistance at childbirth. Arrangements had been made by the responsible authorities for the more thorough training in obstetrics of the pupil midwife and the medical student, but the large number of women qualifying for the C.M.B. certificate made it difficult for the medical schools to provide their students with as full a training and experience as was required, and, along with other matters, including the administration of maternity benefit, the Ministry was now giving attention to the question of how far it was expedient to have an enrolment of upwards of 63,000 certified midwives while less than a quarter of them were actually practising midwifery. On the motion of Lady Barnett a resolution was carried pledging the meeting to do all in its power to reduce the present unnecessary suffering and death rate in childbirth, and calling for skilled medical and midwifery services to be made readily available. To this end the resolution urged improved midwifery training of medical students and midwives, and such readjustment and extension of the provisions for maternity under the National Health Insurance Act as might be necessary, together with an extension of the work of the public health authorities and other bodies in the provision of clinics and welfare centres and health visitors.

#### SCHOOL OF HYGIENE AND TROPICAL MEDICINE

THE annual meeting of the Court of Governors of the London School of Hygiene and Tropical Medicine was held on October 31st in the Council Room of the British Medical Association, Tavistock Square. Sir Holburt Waring was re-elected chairman, and presided. The report of the Board of Management contained a reference to the recommendation of the committee appointed by the Minister of Health on the way in which clinical and pathological facilities for the study of tropical diseases could best be secured. The recommendation was that an imperial hospital with 150 beds should be established. Apart from the need of facilities for study and research, the committee emphasized the pressing necessity for further hospital provision for sufferers from tropical diseases. On both grounds it was thought that the proposed scheme would have a strong call on the support of the business community interested in the economic development of tropical and subtropical countries. It was estimated that a capital sum of £250,000 would be required, and it was hoped that a strip of land in Milet Street forming part of the Bloomsbury area required by the University of London might become available. It seemed probable that the

school might be asked to co-operate with the Colonial Medical Research Committee in the establishment of schemes of research in various parts of the Empire, and the Academic Board of the school was prepared to draw a programme of research in tropical medicine. A question under consideration was the need for the expansion of the work of the Institute of Agricultural Pathology on imperial lines, and proposals had been made to the Empire Marketing Board for its financial support. A medical course in tropical medicine (the full course extended to twenty weeks) had been a success, but the propriety of providing a short intensive course for medical practitioners who had to go to the tropics at short notice was under consideration, as was also the institution of a short course in hygiene for persons employed by banks and firms engaged in tropical commerce and industry, and others who were going to reside in tropical or semi-tropical climates. The need for a larger supply of trained bacteriologists was urgent, and new courses of study had been established in bacteriology and immunology, directed by Professor W. W. C. Topley, and in epidemiology and vital statistics, directed by Professor Greenwood. It was also desired to establish a chair of public health with a view to the appointment of a professor in the group of subjects comprising the principles and practice of preventive medicine, general sanitation, and public health administration. Consultation with local authorities and other bodies would be necessary, but the Board considered that in organizing the division the director, Dr. Andrew Halloway, should at once have the help of the professor designated. As to finance, it was reported that the University Grants Committee had promised to increase its grant of £7,200 made in 1926-27, to £18,000 in 1927-28. This money was needed for new courses of study, and it had been proposed that £25,000 a year promised by the Government would not be adequate. A note had therefore been sent to the University Grants Committee, containing an estimate that an Exchequer grant of £50,000 a year would be required in a full working year. An appeal would also be made to the Colonial Medical Research Committee to obtain additional financial support from colonial sources.

#### AMYOTROPHIC PARALYSIS AFTER INJECTIONS OF ANTITETANIC SERUM

AMONG the various manifestations of serum disease, what grave and persistent, though fortunately rare, form is paralysis with muscular atrophy. Of this La Paré collected and reviewed twenty-five examples, eighteen of which occurred after the use of antitoxic serum. Various explanations of these cases have been proposed, the usually accepted being that it is due to peripheral neuritis or inflammation of the nerve roots. Veigier, Aubertin, and Delmas-Marsalet have recently reported two cases of amyotrophic paralysis after the administration of antitoxic serum, and have argued in favour of the view that the change is in the spinal cord, they agree that the paralysis is more frequent after antitoxic serum than after any other kind of antitoxic serum, but contend that it is not anaphylactic, it is due, they think, to the toxicity of the antitoxic serum towards the central nervous system. From critical analyses of their two cases they conclude that the paralytic phenomena correspond to those of an acute poliomyelitis of the Hone-Melnic type rather than to those of multiple neuritis or myelitis. A detailed discussion of the character of the changes leads to the same conclusion. One of the cases showed a dissociation of sensation the record of which was tabes and radiculitis, and the change in temperature, pain and temperature resembled those of the

syndrome much more than those of multiple neuritis or radiculitis, in this case the presence of lymphocytosis in the cerebro-spinal fluid was held to afford evidence of meningeal irritation, and the spontaneous pains, which might be regarded as suggesting neuritis, are ascribed to the myelitis. In this connexion attention is directed to the severe pain that may accompany Hemo-Medin disease and to severe pain produced by the laceration of the cord necessitated in removal of an intramedullary tumour causing Brown-Sequard's syndrome. The muscular tenderness on pressure is regarded by the authors as very fallacious evidence of multiple neuritis, as it is present in adults with acute poliomyelitis. The selective paralysis of certain muscles, such as the serratus magnus is explained by the consideration that the anterior cornu cells, though histologically alike, differ in their functional activities and physico-chemical reactions.

#### MODERN MIDWIFERY

DR W. J. YOUNG of Harston evidently enjoys the practice of midwifery, and is strenuous in his endeavours to mitigate the risks and pains of labour. In July last he gave his presidential address to the Cambridge and Huntingdon Branch of the British Medical Association under the title "Then and now in midwifery." Dr Young thinks that, with "twilight sleep," morphine, chloroform, and spinal anaesthesia, together with the use of as-traction forceps, we have attained as near to perfection as possible in relieving the sufferings of parturient women. He is not happy, however, about the extended employment of midwives, which he regards as reactionary and likely to perpetrate a large amount of preventable suffering. But a comparison of the management of labour a hundred years ago and to-day convinces him that enormous advances have been made, that the growing practice of ante-natal care, and the negligible risks attached to formidable obstetric operations, have contributed much to these advances, and that the elimination of sepsis, if it can be accomplished, will completely crown the achievements. He attributes the apparent callousness of old-time accoucheurs to the spirit of the Middle Ages—a spirit which did not concern itself with physical pain, but was greatly occupied with spiritual sufferings. It is thus that he accounts for the long delays in the second stage, even after forceps had come into use, so that sometimes the head was left in the pelvis, or even on the perineum, for many hours, while resort was had to such practices as bleeding. Dr Young illustrated his discourse with references to many famous persons from the mother of Socrates, who regaled her son with stories of the sufferings of her patients, to Mrs Jarvis of Clerkenwell, who was delivered, "after three mortal hours of the crochets," in 1830, and from Helvir, the mother of Cicero, to Louise de la Valliere, for whose birth Louis XIV introduced male accoucheurs

#### TRACHOMA IN CHINA

IN 1925 Dr Harvey J. Howard, professor of ophthalmology in the Peking Union Medical College, was captured by bandits. His experiences are told in graphic but modest fashion in a book entitled *Ten Weeks with Chinese Bandits*. He was on a visit to his friend Major William Morgan Palmer, an Englishman who had done good service for China, and had initiated a most promising experiment in agriculture in Northern Manchuria which, had his life been spared, would probably have done much for the relief of economic conditions in that country. Alas! raiding bandits attacked one of the outlying farms of the estate, and in an attempt to frighten off the invaders he was shot dead. The professor, who was with him at the time, was

carried off into captivity and held to ransom. He encountered some amazing experiences, and endured much hardship in the hurried flight of the bandits when they were pursued by numbers of troops sent out to rescue him. Ultimately he was released. Dr Howard found disease rife among his captors, and considered that opium was at the root of most of their degradation. Some of them were men of high culture, and had held important positions in the civil and military life of the country. One of his captors, a man of education, suffered badly from trachoma, and was on the verge of blindness from corneal ulceration of both eyes. By reason of his ability to relieve him of pain and stay the symptoms, this man became his protector, and probably saved him from being killed. The manner in which he treated this case, and severe wounds that threatened to become gangrenous, when there were no medicaments at hand shows what can be done when simple measures are applied with intelligence.

#### SIR CHARLES J MARTIN

THE appearance of Professor C. J. Martin's name in the recent list of Knights Bachelor created on the occasion of the King's birthday was most cordially welcomed by the staff of the Lister Institute as a well deserved tribute to one who had gained high scientific distinction, and who during the past twenty-four years had so happily guided the fortunes of the Institute. At a special meeting of the staff it was decided that the occasion might fittingly be celebrated by presenting Sir Charles Martin with his portrait as a token of their personal esteem and their appreciation of his great services to the Institute. Subscriptions to the portrait were confined to present staff and research workers and to past members of the staff during Dr Martin's directorate. The painting of the portrait was entrusted to Mr Neville Lewis, and the finished work has given much satisfaction. The portrait was presented at a meeting in the library of the Institute on October 28th, when Professor Harden, F.R.S., presided over a large company of past and present members of the staff and research workers. As one of the few members who could recall Dr Martin's arrival as director in 1903, Professor Harden referred in eloquent terms to the scientific and administrative ability of the director, his versatility and helpfulness, and, above all, to his great personal charm and tact, which had conduced so greatly to that domestic harmony and camaraderie which had ever been the pride of the Lister Institute. Sir Charles, in returning thanks for the portrait, alluded to the great good fellowship among staff and workers which had rendered so pleasant the years he had spent among them.

#### J & A CHURCHILL.

THE medical publishing firm of J and A Churchill, long associated with Great Marlborough Street, has lately moved to larger premises at Nos 39 and 40, Gloucester Place, Portman Square, W. 1, at the corner of York Street. The firm was founded in 1825 by John Churchill, grandfather of the present partners. For many years the two sons of the founder, John and Augustus, had charge of the business, and each in turn introduced a son, Mr A. William Churchill, M.A., and Mr J. Theodoro Churchill, who jointly carry on the tradition of the house. Members of a profession which has for over a hundred years had friendly dealings with this firm, as publishers of the *Medical Directory* and of many standard medical works, will wish it continued prosperity in its new office, which incidentally brings Messrs Churchill within easier reach of most of their authors and collaborators. In a pamphlet announcing the change or address there appears an impressive list of medical writers, past and present, whose books have borne or now bear on their title-pages the familiar imprint

<sup>1</sup> *Ten Weeks with Chinese Bandits*. By Harvey J. Howard, M.D. London: John Lane, the Bodley Head Ltd., 1927. (Pp. 272. E. 6s. net.)

## THE PATHOLOGY OF PNEUMONIA \*

BY

J F GASKELL, M D, F R C P,

ASSISTANT PHYSICIAN, ADDENBROOKS HOSPITAL, CAMBRIDGE

Dr GASKELL said that his purpose was to submit the results of certain experiments which had occupied him during the last seven years and had yielded, as he thought, certain facts which could be legitimately applied to man. They showed that the title of the infecting organism was all-important, and that this determined both whether a lesion would be produced at all and what the nature of that lesion would be. An attack of lobar pneumonia in the healthy adult was due to organisms of titres between 5 and 7, which were otherwise comparatively rare. The deduction might be made that it was spread by direct contact, infection passing from throat to throat, though very possibly intermediate carriers were often concerned.

In any attempt to produce infective lesions by experiment estimation of the virulence of the infecting organism was of the utmost importance, this was particularly so in the case of the pneumococcus, because its virulence varied so greatly. Earlier workers used organisms which answered the criterion that one-millionth of a cubic centimetre of an eighteen hours' broth culture killed mice when injected intraperitoneally, their method of obtaining such a dose was by successive dilutions in broth. This criterion was open to the objection that the few organisms injected lay in a comparatively large volume of a nutrient fluid which was not rapidly absorbed and in which they could multiply freely, the host acting as a living test tube. The method, therefore, did not give an accurate measure of the minimal lethal dose to mice.

The virulence or pathogenic power of an organism depended upon two factors which could not be measured separately—namely, the invading power of the organism and the resisting power of the host. In order to obtain any measure of virulence it was necessary, therefore, to standardize as far as possible one of these factors—namely, host resistance. The measure then used is the smallest dose of the organisms which will cause death. It was, therefore, essential to employ a method which ensured immediate reaction between the attacking organisms and the defences of the body. The organisms must be denied all facilities for multiplying other than those provided by the tissues of the host. The mouse was an experimental animal eminently suitable for the measurement of pneumococcal virulence, owing to its high susceptibility, and if healthy mice whose weight lay within narrow limits were used a fairly satisfactory stabilization of the host factor was obtained. The possibility of variation of the measurement of the dose of the organism by multiplication in the fluid introduced could be obviated by dilution in normal saline, which was rapidly absorbed. Such dilutions must, however, be injected immediately, as the pneumococcus rapidly died in saline solution.

His own experiments had been almost entirely carried out with a single strain of pneumococcus whose virulence had been altered at will. For convenience the measure of virulence or titre had been taken as the logarithm of the reciprocal of the minimal lethal dose—that was to say, the titre being 8, the minimal dose was  $1/10^8$ . The actual dose given could be roughly estimated from the fact that an eighteen hours' broth culture contained between 200 and 500 million organisms, or otherwise  $2 \times 10^8$  to  $5 \times 10^8$ . The minimal lethal dose at titre 7 therefore lies between 20 and 50 cocci only, and titre 8 becomes an absurdity.

The experimental animal selected was the rabbit, an animal moderately susceptible to the pneumococcus, which fortunately showed very comparable to the human host in its relationship to infection.

## Lung Structure

Dr Gaskell said  
In the mammalian lung the bronchial tree is lined with ciliated epithelium up to its terminal branches, which end in one or two terminal bronchioles having non-ciliated epithelium.

\* Being an abstract of the Bradshaw Lecture delivered before the Royal College of Physicians of London on November 3rd.

each of which opens into an alveolar unit consisting of a number of portions, which have been accurately described by Millier. The terminal bronchioles are lined by ciliated epithelium, the alveoli, the air sacs, and air vesicles with terminal pores. Owing to the absence of ciliation of these terminal bronchioles any material which reaches into or beyond them is not removed, but is speedily sucked in by the respiratory movements and is bound to become spread through the system. Such a terminal bronchiole with its air spaces is termed an alveolar unit, and any infection which reaches it necessarily involves the whole unit.

These terminal units not only occur at the end of the branchings, but are also given off throughout the bronchial tree, rising from the largest bronchi, usually being in pairs and connected to such a bronchus by only a very small distal bronchiole. The central part of the lung is composed of these units, which are thus in very intimate connexion with the biggest bronchial tubes.

Owing to the respiratory to and fro current and the primary action of the epithelium, material lying in the largest bronchi is rapidly side-tracked into these central units. There is a tendency for these small branchings consisting of a terminal bronchiole with two units attached to occur in whorls of three, a peculiarity of structure which explains the trilobed appearance of the consolidation not infrequently seen in bronchopneumonic conditions.

## Method of Experiment

Dr Gaskell then described the method he employed to make certain of introducing pneumococci into the lung itself.

Tracheotomy was performed, and a soft rubber tube of a size as to engage in the opening of the main bronchus to a depth of the lung passed down the trachea. The culture was injected into the tube by piercing it with a fine injection needle, and the material blown into the lung by means of a glass ball on the external end of the tube. It was found that the most common site of any lesion produced was the base of the right lung, which is of interest, because of the frequency with which this lobe is the site of pneumonia in man. The probable explanation in both cases lies in the fact that the bronchus of the right lower lobe is in the most direct line with the trachea. As a rule 1 cm. at least of the culture was injected, and it was estimated that about half reached the lung itself, the remainder being lost in the tube. Over eighty experiments were performed with the Type 1 pneumococcus whose virulence varied from a titre of below 3 to one between 6 and 7. The nature of the lesion obtained depended entirely upon the virulence of the organism used, and not upon the dose given.

## Broncho-pneumonia

When organisms of about titre 4 were introduced into the rabbit's lung, they and the material in which they were contained were speedily side-tracked by the respiratory current and ciliary movement into the nearest distal bronchi. Frequently the material had reached only the terminal bronchi and had been side-tracked into the central units in connexion with them, thus giving rise to a patchy central pneumonia, if the material had spread more widely a diffuse broncho-pneumonia was produced. The inflammatory reaction which took place remained confined to the units thus invaded, which were often in the earlier stages clearly delineated by the consolidated area. It was only in the early stages that cocci in any quantity could be identified in such a lesion. They appeared to have lost their power of multiplication and to be rapidly destroyed by the inflammatory reaction, though, as would be expected, shortly, this destruction was not always complete. In the neighbouring alveoli began to take part in the inflammatory reaction, so that the unit outline became obscured.

The capillaries of the consolidated patch became more and more engorged, reaching a maximum at about the fourth or fifth day. They then gradually became more conspicuous, and in the meantime the more fluid exudate became slowly absorbed by local lymphatics.

These experiments threw light on that low grade type of broncho-pneumonia which occurred in children, characterized by the successive appearance of fresh patches of lung infection which might even continue for several months. The explanation they suggested was that the local defensive reaction in the original lesions had not been sufficiently intense completely to destroy the material

### Lobular Pneumonia

As the virulence titre of the invading organism increased, though the initial stages of the cleansing of the bronchi and side-tracking of the infecting material were the same, the inflammatory reaction became both more extensive and more intense in nature. The power of the cocci rapidly to reproduce themselves was increased, so that they were much more easily found in the earlier stages, and were no longer confined by the limits of the alveolar unit, but spread directly into others lying around it. The nature of the inflammatory reaction was changed owing to an increase of the numbers of polymorphonuclear leucocytes and consequently a diminution in the preponderance of the larger alveolar cells. The serous exudate was increased and fibrin might begin to be formed in it.

The capillaries again became more and more engorged up to about the fourth day, but then, especially in the centre of the patch, they became rapidly obliterated by the pressure of the exudate in the alveoli. It was during this early period that cocci were most conspicuous. Though the inflammatory patch had become much larger, its periphery was still similar to that of the smaller patch with catarrhal exudate taking place at a fairly early stage. These patches might become so large that they coalesced to form the more extensive lobular type of lesion.

### Lobar Pneumonia

With a further rise of titre to a value of between 5 and 6, if a suitable dose was introduced a lobar lesion was obtained. The organisms had now a much greater power of reproduction and invasion, and spread rapidly throughout the lobe, being apparently able to keep in advance of the host's attempt to localize them by inflammatory reaction until the periphery of the lobe was reached. A lobar lesion twenty-four hours old showed the process clearly.

In this lobar form of lesion the distension of capillaries did not reach its maximum till about the fourth day, after which the capillaries became somewhat suddenly obliterated by alveolar pressure. The lymphatic system became widely dilated throughout the lobe, distension reaching a maximum at about the third day. The large lymphatics round the larger vessels were then extremely conspicuous, and the bronchi and bronchioles were widely involved. They were filled with exudate and merged into the general consolidation. Cocci were most conspicuous at the spreading edge in the earliest stages. They could easily be found up to the third day, with much more difficulty on the fourth day, and had practically disappeared by the fifth day.

### Lymphatic Drainage

In a few experiments at the lobar titre the involvement of the lymphatic system might cause fatal results. Though the lymphatic channels contained all sorts of debris which must have been derived from the alveoli of the lung free cocci were, as a rule, completely absent, only an occasional polymorphonuclear cell contained them, and the contrast was great between the wide lymph channel and the alveoli next to it, in which free cocci were numerous. Occasionally an intense invasion of the whole lymphatic system had taken place and the picture was reversed.

These results were perhaps of wider and more general application. They indicated that the swelling of the lymph gland, which belonged to any inflamed tissue, was usually caused by debris drained from the part affected, which was in itself sterile except for the presence of organisms which as a rule, were safely enclosed in leucocytes, and became filtered out in the peripheral sinuses of the lymph gland. Such organisms were mostly killed by the leucocytes, if all were destroyed the gland subsided without breaking down but if some were successful in destroying their host, the gland then suppurated.

Occasionally, however, an infection was of such virulence that the power of resistance of the peripheral lymphatics became destroyed. The lymphatic system draining the part underwent a true invasion and acute lymphangitis occurred.

### Invasion of the Blood Stream

In all experiments where definite lesions had been obtained and the animal had been killed on the first or second day, blood cultures yielded positive results. By the fifth or sixth day, even when the lesion was severe

the blood culture had almost always been sterile. Thus organisms were always present in the blood at the earlier stages.

### Pleurisy

The relation of pleurisy to lung lesion varied very considerably. An intense form of double pleurisy and pericarditis might occur with titres of high virulence, and probably developed with extreme rapidity, beginning within twenty-four hours of invasion. Pleurisy has also been found with milder types of lesion due to cocci of lower virulence in connexion especially with the lobular type of lesion. In its mildest degree it consisted of a patch situated over a lobular lesion which had just reached the surface, the patch then had been found to be sterile at all stages. When the lung lesion was larger, the pleurisy, though local, was sometimes infected, but usually when this had taken place the whole pleural cavity soon became involved and considerable effusion occurred. A lobar lesion had also been accompanied by unilateral pleurisy with effusion.

### Pericarditis

In a few experiments the pericardium alone became infected, both pleural cavities escaping. The relationship of the root of the lung to the pericardium being very close, an infection mainly localized to the central region of the lung near the root could reach the surface, where it lay against the pericardium and directly invaded this cavity. Such pericarditis, if recovered from, gave rise to adherent pericardium, which suggested that certain cases of this condition might arise from a pneumococcal infection by way of the lung.

### Crisis

On the strength of the facts above described Dr Gaskell attempted an explanation of the crisis in lobar pneumonia. He said:

I have already stated that cocci have practically disappeared from the lung on the fifth day, but are usually easy to find in the more severe lesions until then. Now the chief toxin of the pneumococcus is an endotoxin which is only liberated when the cocci are killed. There is thus an increasing liberation of endotoxin up to the fifth day, but after that the supply practically ceases. One of the factors determining the crisis may therefore be the final neutralization of endotoxin by the defences of the body forty-eight hours later on the seventh day. Another extremely interesting phenomenon has been demonstrated by Armstrong. He has shown that in lobar pneumonia the protective power of the serum which is extremely slight at the onset of the disease, practically vanishes after twenty-four hours and remains absent for the first four days. On the fifth day it suddenly reappears and increases enormously and with great rapidity to a maximum on the seventh or eighth day. It then slowly diminishes, throughout convalescence. The rapid rise of this power to destroy pneumococci coincides with the crisis. The combination of these two processes thus affords some explanation of the regularity with which crisis occurs on or about the seventh day.

### Low Virulence Organisms: Terminal Pneumonia

No experimental method of lowering the resisting power of the host had been attempted, but Dr White had been approaching the problem of the nature of terminal bronchopneumonia from the clinical side, and had also attempted to correlate the titre of organisms obtained from human lung lesions with the experiments Dr Gaskell had described. He had had the opportunity of examining strains from a considerable number of cases of pneumonia, extending over nearly two years, which had occurred in a somewhat isolated village near Cambridge the outbreak had therefore been due to the nature of an epidemic. The titre of the strains recovered had been remarkably constant, and the number of the inhabitants of this village being comparatively small, it was possible to draw up a scheme of the path of infection had probably taken. In this instance a pneumococcus of high titre had therefore been definitely traced from case to case by actual direct contact. These results opened up the prospects of control of pneumococcal infection in so far as lobar pneumonia in the healthy adult was concerned, and pointed very strongly to the necessity of the isolation of this type of disease. The occurrence of pneumococci of titre 5 or over in the human throat was undoubtedly very uncommon, the organisms with pneumococcal reactions which were present were almost always of quite low titre.

## England and Wales.

### ST THOMAS'S HOSPITAL DINNER

THE old students' dinner of St Thomas's Hospital was held on October 28th, with Sir Charles Ballance in the chair, at St Thomas's House, the splendid new residential club for students in Lambeth Palace Road, opposite the entrance to the Medical School. A description of the building and of the opening ceremony performed by the Archbishop of Canterbury appeared in our issue of April 30th, 1927. Among those who supported the chairman on Friday evening last were Sir John Rose Bradford, President of the Royal College of Physicians, the medical heads of the three Services—Surgeon Vice-Admiral Arthur Gaskell, Lieutenant-General Sir Matthew Fell, and Air Vice-Marshal David Munro—Sir James Berry, President of the Royal Society of Medicine, Dr E W Ainley Walker, Dean of the School of Medicine at Oxford, and Professor H R Dean of Cambridge, together with Sir George Makins, Sir Hector Mckenzie, Dr T D Acland, and other past and present members of the staff of St Thomas's, the Treasurer (Sir Arthur Stanley), and Lord Riddell, one of the Governors. Sir Charles Ballance, in proposing the toast of prosperity to St Thomas's Hospital and Medical School, gave some recollections of the time when he was a student in College House fifty years ago. Coming to more recent days he congratulated two old students, Dr C H Vernon on winning the King's prize at Bisle, and Dr Percy Smith on vindicating in the law courts his professional and personal honour. Sir Arthur Stanley expressed the hope that St Thomas's House, as a real centre of good fellowship, would prove to be a home and club for all students past and present. Sir Cuthbert Wallace, Dean of the Medical School, who also responded to the toast, referred to the loss by death of three distinguished old students, J L Adams, Sir Bryan Donkin, and J H Tonking—"the surgical father of Devon and Cornwall", congratulated Sir C T Martin and Sir Frigolani Buzzard on their recent honours, and paid a tribute to Sir Charles Ballance for his thoroughness and largeness of view, and his loyalty to younger men and to the institutions he served. The health of the guests was proposed by Mr Percy Sargent, who coupled with the toast the name of a successor and worthy competitor of John Hunter—Sir Arthur Keith. In his reply Sir Arthur Keith congratulated St Thomas's students on their gorgeous new club rooms, and spoke of his own debt to St Thomas's for its courteous reception when he first came to London as a shy Aberdeen lad, and for the friends it had given him like George Makins, Charles Ballance, Cuthbert Wallace, and F G Parsons.

### KING EDWARD'S HOSPITAL FUND FOR LONDON

In certain respects the statistical report for 1926 on the finance of London hospitals, which has just been issued by the hospital committee of King Edward's Hospital Fund for London, is the first of a new series, as compared with those of previous years the present statement is larger and ever more interesting. A footnote on an early page recalls that the issue of these reports began with that for the year 1903, and was printed for private circulation only, as were those of the four following years. The first public report appeared in 1909, and contained the figures relating to sixty-six hospitals for the previous year. A new series began in 1922, when an analysis of the general fund income was added, and now, again, change has been rendered necessary by the revision of the system of hospital accounts and the extension of the Fund's area of operations from a radius of seven miles to one of eleven. The present report deals with 134 hospitals individually and collectively, coloured graphs have been added to indicate the gratifying progress during the past five years. The available beds increased from 13,270 in 1922 to 14,170 in 1925, and 14,470 in 1926. The in-patients numbered 209,700 in 1926, as compared with 194,200 in 1925, and 167,900 in 1922. Out-patient attendances have grown from 6,357,000

in 1922 to 7,163,000 in 1925, and 7,455,000 in 1926. The total cost incurred was £3,058,000, an advance of £700,000 on the year 1925 and of £407,000 on 1922. An analysis of the cost of working at each separate hospital is compared with the average cost for the particular group, the case of the teaching hospitals, for example, the average was £234 for each occupied bed. In an appendix to the report there are tables showing the consumption of certain articles of food on a basis of 100 persons per day, for patients and staff separately and combined. The cost in 1926 was £3,019,000, as compared with £2,485,000 in 1922, an increase of £534,000. Between 1925 and 1926 there was a drop of £103,000, due mainly to a large fall off in legacies. The result was that after an aggregate surplus for each of the years 1923, 1924, and 1925, 134 hospitals had an aggregate deficit of £39,000 for the year 1926, when the number of hospitals with deficits was fifty-five, while seventy-nine had surpluses. Of the total expenditure of £3,058,000, about £586,000, or 19.2 per cent, was covered by income from investments and £983,000, or 32.1 per cent, by patients' payments and other receipts on account of services rendered, while £1,432,000, or 46.8 per cent, was provided by voluntary contributions, including legacies. The total income was 98.7 per cent of the expenditure, leaving a deficit of 1.3 per cent. In addition to the general fund income for maintenance purposes, the hospitals received £280,000 in endowment, and raised £479,000 for building and equipment, bringing the total receipts in 1926 to £3,778,000. The amounts received for buildings and equipment have permitted a steady increase in the number of available beds, as well as other extensions and improvement. The hope is expressed that this report will assist hospital managers to check any excessive expenditure, reducing it whenever it cannot be justified and thus following one of the recommendations of Lord Cive's committee for the re-establishment of the finances of the voluntary hospital system.

### COUNTRY HOSPITAL FOR BRISTOL CRIPPLED CHILDREN

As stated in a previous issue the Bristol Crippled Children's Society and the Bristol Orthopaedic Hospital have amalgamated. The joint body has bought 65 acres of land at Winford in Somerset for the erection of an open air hospital school for non-tuberculous crippled children. This site, approved by Sir Robert Jones, is on a spur of the Mendips six miles from the centre of Bristol. Here there will be ample room for expansion and space enough to provide country annexes to all the city's hospitals should the need arise. It is proposed that a hospital with three wards of sixty beds each should be built, and work will shortly be started on the first ward with its operating theatre and administrative block. The fund of the joint body amounts, at present, to £20,000. It is estimated that at least £40,000 is needed for the erection of the first ward, and £10,000 for each additional ward. When the new buildings have been erected the support from local bodies such as the Education Authority, and others will be sufficient to make the institution pay its way. The experience of other open air schools amply proves that the greater the number of minutes the mother spends in maintenance for each child, and the better the progress of the society avoiding any further appeal to the generosity of the public.

### R A F HOSPITAL AT HALTON

A new hospital for the Air Force was opened at Halton by Princess Mary Viscountess Lascelles on October 3rd. Sir Samuel Hoare, Secretary of State for Air, and the Government were not intended to duplicate hospital facilities where military, naval, and civil hospitals were already existing. Last year some 1,200 patients were admitted from the R A F to naval and military hospitals. Halton is the largest Air Force station in the world and the hospital there would be the principal hospital of the Air Force. It contained 204 beds, including twenty for officers and nursing sisters and twenty-three for the wives of officers and airmen. It would admit patients not only from the Air Force station at Halton, but from the Air Force stations outside the range of naval, military, or civil hospitals, and would be a great asset to the Air Force.

<sup>1</sup> Statistical Report on the Income and Expenditure of One Hundred and Thirty Four London Hospitals for the Year 1926. London: Spottiswoode, Ballantyne and Co. Ltd 1927 2s 6d net 2d post free.

to get as much sunlight and air as possible and to reduce dust and labour in cleaning its wards were floored with rubber thanks to the generosity of the Rubber Crovers' Association and a flat roof for natural sun treatment had been provided. There was a well equipped operating theatre, to the lighting of which careful attention had been given. The Air Force. Sir Samuel Hoare continued, was rightly proud of its medical and nursing services, and of the splendid work its medical officers and nurses did at home and abroad, often in the face of great difficulties. There was no service where a higher standard of health was so constantly needed, and no service where efficient surgical help was more urgently required to meet the inevitable strain and risks of life in the air.

#### DENTAL SERVICE IN INDUSTRY

In his address, which we reported on October 8th (p. 655), given at the opening of the winter session of the Royal Dental Hospital, which coincided with the inauguration of the John Hampton Hale research laboratory. Sir Walter Fletcher emphasized the importance in preventive medicine of the proper development and preservation of the teeth. The matter is also highly important in industry so that with some firms the worker before engagement is required to possess a properly cared for set of teeth, and provision is made for their maintenance in good condition by dental clinics attached to the work. The Industrial Welfare Society has issued a pamphlet entitled *Dental Service in Industry*, as a guide to firms in establishing dental services. It is stated that not only is efficiency greatly increased if toothache is absent but also that a works dental service leads to a remarkable decrease in illness from indigestion, gastritis, influenza tonsillitis, anaemia, and rheumatism. It is suggested that for young workers the treatment provided should be free of charge but compulsory, the reasons being that children now come from their schools with teeth properly attended to but are not entitled to dental benefit under the national scheme before the age of 21. To older workers charges are made but these are less than the cost of private dental treatment while other advantages accrue to the worker. Thus the treatment is carried out in the firm's time examinations and consultations are free payment is made by weekly deductions varying with the scale of wages and where the treatment is voluntary the firm may find it possible to bear a part of the cost. Large firms with over 3,000 workers may employ full time dentists smaller firms a part-time dentist or one who visits the works once or twice a week. Usually a contract may be made with a local dentist to treat the workers at his own surgery at lower rates than those for private patients. The pamphlet contains a large amount of information about the choice of dentist by employing firms, the construction and appointments of the surgery the organization of the clinic, and the cost involved. Firms are also advised to obtain the co-operation of outside agencies such as the Hospital Saving Association and the approved societies. The value of this advice will certainly be recognized if and when dental treatment becomes a part of the State's responsibility for health. In such event we may presume that well organized dental services rendered by reputable firms will be linked up in some way with the national service.

#### RADIOLOGY IN PULMONARY DISEASES

Under the auspices of the Joint Tuberculosis Council a post-graduate course on radiology in tuberculosis and diseases of the lungs, will be held at the Victoria Park Hospital, from November 21st to 26th. Throughout each day there will be an exhibition of special radiograms, and lectures and demonstrations will be given by members of the hospital staff. The following subjects will be dealt with on the six successive days respectively: the radiogram in non-pulmonary tuberculosis the various stages of pulmonary tuberculosis pulmonary tuberculosis in childhood, the use of lipiodol spontaneous and artificial pneumothorax and pleural effusions, and intrathoracic tumours. Demonstrations will be given also on common errors in radiological diagnosis and on the use of x-ray apparatus. There will be a museum demonstration on anthracosis and the causes of enlargement of mediastinal glands. A lecture on pleural adhesions will be given by

Dr S. R. Glayne. The fee for the course is three guineas, and further information may be obtained from Dr William Brand, the honorary secretary of the post-graduate courses, The Larches, Farnham Royal, Bucks.

## Ireland.

#### DR GAUSSEN OF DUNMURRY

A REMARKABLE tribute was paid to Dr D. P. Gausson of Dunmurry, co. Antrim, on October 25th, when a meeting attended by a large number of persons of every class and creed was held to present a testimonial and address to him. The chair was taken by the Right Hon. J. Milne Barbour, M.P., Minister of Commerce for Northern Ireland, who said that Dr Gausson was leaving after occupying the post of medical officer for forty-two years. He was the friend of all, had aided them in their hours of trial, and had given of his best to all on every occasion, he had taken a leading part in sport and in all the activities of life, and when the war came he had offered his services and had gone out for his country. Mr. Barbour then presented to Dr Gausson the address, to which more than six hundred persons had appended their signatures, and a cheque. Miss McCance handed to Mrs. Gausson a fine silver salver, and spoke of her valuable services on all occasions. Numerous others spoke and bore testimony to the high qualities of Dr. and Mrs. Gausson. Dr. Hunter, as a brother practitioner, gave expression to Dr. Gausson's worth. Dr. Gausson had been president of the North of Ireland Branch of the British Medical Association and of the Ulster Medical Society, and stood amongst the highest in the local ranks.

#### KNOWING EXPECTATION OF LIFE

Professor Joseph W. Bigger, M.D., president-elect, Dublin University Biological Association, gave an address on the expectation of life and the bacteriological laboratory. One method of ascertaining the expectation of life was that used by insurance offices where premiums were regulated by a table known as the O.M. table, which had been constructed from the actual experience of sixty British insurance offices between the years 1863 and 1893. A second method was founded on the census returns and the deaths registered in a single year or over periods of three or ten years. The life table method reflected faithfully the healthiness or otherwise of the particular year or period of years. According to the latest life tables of England and Wales, those based on the experience of the years 1920 to 1922, a male aged 25 years had an expectation of 44 to 48 years. According to the O.M. table the expectation of life was 39.55 years. The expectation of life was now greater for all males, healthy and sick together in England and Wales by about five years than it appeared to be for those carefully selected men who insured their lives. Medical science was constantly advancing—now along one line now along another. At one time physiology showed the most marked progress. That was followed by bacteriology and to-day biochemistry was spreading new and attractive vistas. Bacteriology was still a new subject it was little more than fifty years since thanks chiefly to the work of the two intellectual giants Pasteur and Koch, bacteriology was firmly established as a science—an appreciation of the facts of which were necessary for any real understanding of medicine and surgery. In conjunction with pathology the action of bacteria on the human and animal bodies was investigated, and the methods by which the body resisted carefully examined. Bacteriologists made no nice distinctions as to the animal and vegetable kingdoms in the early days, for all disease was then province. Questions of transmission of disease were also being investigated and it was soon realized that man might be infected not only by another man but also by animals, as in anthrax and tuberculosis. The practical importance of these discoveries could not be over-emphasized for by knowing how and by what insect a disease was spread they could frequently stamp out the disease. It was not unfitting, the lecturer said, in this connexion to recall the death of Adrian Stokes, he had to use his

diseases. Accurate diagnosis was half the battle in itself, but neither the State nor the local authorities had the assistance of the laboratory. In most civilized countries facilities for laboratory diagnosis and for the detection of carriers of infectious diseases were available, but here lagged behind. The time had come, Dr. Biggar (continued) for the public to realize what hygiene could do, and to insist on it being done in order that the present generation might reap the harvest that bacteriology had sown as it was being reaped in other countries. It was time that Ireland should follow this lead, and engage in serious efforts to prevent those diseases which were known to be preventable.

GENERAL COUNCIL OF EDINBURGH UNIVERSITY

The statutory half-yearly meeting of the General Council of the University was held on October 28th. Principal Sir Alfred Ewing presided over a good attendance. Dr R McKenzie Johnston, one of the assessors appointed by the Council of the University Court, having intimated that he did not wish re-election, the two assessors to the University Court appointed were Alexander Miles, MD, FRCS, and Sir Norman Walker, MD, FRCP. Reference was made to the loss which the University had sustained during the past session by the death of Professor Harvey Littlejohn of the chair of forensic medicine. A draft ordinance for the foundation of a Buchanan chair of animal genetics was considered, and it was intimated that the University Court had received gifts towards the department of research in animal breeding as follows: £10,000 from the International Education Board, New York, £10,000 from Lord Woolavington towards the endowment of the chair, £20,000 from the International Education Board and £16,000 from the development commissioners towards the cost of buildings, and £10,000 from the Empire Marketing Board, with £1,000 from the Highland and Agricultural Society, towards endowment. A report was received regarding a conference of representatives from the various Scottish universities which had been held at Perth in March regarding the status of doctors' degrees. It had been decided that the degree of DD and LL D should be continued to be conferred *honoris causa* only. This was approved by the University Council. It was intimated that the University Court had approved of certain changes in the clinical examination for the MD degree. The examination for this degree would, in future, consist of two parts—a major and a minor—to suit the experience of bachelors in medicine who had been working along different lines. The examination might, in future, be taken with the major part, consisting of clinical medicine and some special branch of medical science or practice possessed by the candidate, and the minor part, or the examination might be so fixed that the major part consisted of a special branch of medical science or practice possessed by the candidate, together with clinical medicine as the minor part. An application of the Council brought out some interesting figures as regards the numbers attending Edinburgh University. The number of graduates on the roll of the General Council at January 1st, 1927, was 16,855, as compared with 12,222 on the corresponding date in 1914. The total of related students in the year 1926-27 was 4,139, as compared with the average figure of 4,038 for the previous ten years. In the medical faculty the number of matriculated students in 1926-27 was 1,017, as compared with 924 in the preceding year, and 1,055 two years previously. The increase in the number of medical students is shown more emphatically by the fact that the number of first year students entering the medical curriculum was 242 in 1926-27 as compared with 177 in 1924-25, and compared with an average of 189 for the preceding five years. The income of the University for the year ended July 31st 1926 has been £243,170, as against an expenditure of £214,267, leaving a surplus of approximately £28,000. The sum received for fees for tuition, examination, etc., was £93,730, while the sum paid in salaries of the teaching staff was £130,000.

Dr. Bigger went on to trace the connexion between the expectation of life and the bacteriological laboratory. Expectation of life might be increased by postponing the age of death, or, what amounted to the same thing, by preventing avoidable death. In what way could the biological laboratory do that? There were five chief functions of the laboratory, each with its own influence on public health, these were research, diagnosis, control, prophylaxis, and therapeutics. Of these, research was by far the most important, and sufficient had been said to make clear how much could be done by research to demonstrate the cause of many infectious diseases. To illustrate the influence of the bacteriological laboratory on the expectation of life the lecturer submitted tables showing the expectation at various age periods in different years. The expectation of life in 1920-22 was greater by fourteen years than in the period 1871-80. In the last half-century the death rate had fallen by 21 per cent. Apart from figures, however, no one would deny the great advance of surgery in the half-century, and the number of lives now saved which fifty years ago would undoubtedly have been lost. He made the bold claim that for virtually all the advances made by surgery, for nearly all the lives saved, the credit must be awarded to bacteriology. It had been estimated that the total number sick at any time throughout the year was about double the number of deaths occurring during the year. In the Irish Free State, in 1925, more than 43,000 deaths occurred, and, on that basis, 86,000 were sick every day. By saving one death, particularly one death from an infectious disease, many days of sickness and the cost of treatment were saved and the labours of the sick permitted to enrich the country. Many years ago the value in potential labour of an English agricultural labourer was assessed at £200. On that basis the Free State lost £8,600,000 each year in the deaths of its people. He did not wish to stress unduly the financial aspect, for the pathos of unnecessary death should in itself be a sufficient spur to fresh achievement, but he realized the truth of Andrew Balfour's dictum "Demonstrate material monetary benefits resulting from hygienic measures and you may easily the day." That hygiene did pay, and pay handsomely, was just beginning to be realized. The people of Ireland should understand these facts. The first thing, perhaps, was to teach hygiene better to the medical student, to teach him normality and prevention, rather than abnormality and disease. Such incidents must be prevented as that reported from a village in County Dublin the other day, where the medical officer condemned the water supply because five cases of diphtheria had occurred. Instruction must be given in the schools, but an attempt must also be made to reach the adults by posters and handbills and through the newspapers. Not only the public, but the local authorities, and even the Government departments, were lacking in vision. The medical men engaged in the public health service were, for the most part, wretchedly paid, and in a number of recent cases country authorities were unwilling to appoint medical officers on grounds of economy. Such is the filsest of false economy, for a country which is not prosperous cannot afford to indulge in the luxury of ill health. It would be a very inefficient medical officer of health who could not save twenty lives a year—a saving surely worth £1,000, without considering the corresponding saving in sickness. Dr. Bigger said that bacteriology had led to the saving of very many lives, but even with the incomplete knowledge as yet possessed it could save very many more. The way had been pointed out, but the public health authorities had not followed it. Public opinion must force them to do their utmost to save the lives which present knowledge allowed them to save. Cases of infectious diseases were treated in hospitals at the expense of the community, but there was no provision except of the most general description for the prevention of those diseases. Laboratory facilities were available, at the public expense, for the diagnosis of venereal diseases, but what of diphtheria, tuberculosis, enteric fever, and many other

The habitable and invested property of the University amounted to over £1,700,000. The benefactions acknowledged during the year 1925-26 had amounted to over £44,000.

#### MIDWIVES AND MATERNITY HOMES (SCOTLAND) Act, 1927

The Scottish Board of Health has issued a circular to local authorities drawing their attention to the Act of the present year which amends the Midwives (Scotland) Act of 1915 and provides for registration and inspection of maternity homes. The Act came into operation on July 29th 1927. One of the new provisions enacts that any person not certified as a midwife who attends a woman in childbirth may do so only under the direction and personal supervision of a qualified medical practitioner. Protection is, however, afforded to persons attending a case of sudden or urgent necessity. Students undergoing training in midwifery are also excepted. Midwives are given the right of recovering reasonable compensation from the local authority when suspended from practice to prevent the spread of infection. Payments in connexion with maternity and child welfare schemes are also sanctioned. The section relating to medical assistance in case of emergency now provides that the fee paid to the doctor instead of covering "one subsequent visit" shall cover "such further visits as shall be prescribed by the scale" fixed by the Scottish Board of Health. Another section provides that for any areas in which a maternity service and child welfare scheme is not in operation the local supervising authority shall provide the services of a midwife or doctor when necessary with power to recover the fee from the husband or guardian. With regard to registration and inspection of maternity homes, this section of the Act comes into operation from January 1st 1928 and imposes a penalty on any person who therefter carries on a maternity home unless it is registered. The fee payable for registration is to be 5. The registration is effected by the local supervising authority but may be reduced or cancelled if the authority is not satisfied that the person is fit to carry on the home or that the situation, sanitation, accommodation, staffing or equipment is not fit for a maternity home. Homes together with their prescribed records may be inspected by officers of the local supervising authorities and by officers of the Scottish Board of Health. The local supervising authority has power to exempt from the inspection and registration any hospital or similar institution not carried on for profit. Local authorities are instructed in the circular as soon as possible to give notice by advertisement or otherwise to ensure that persons carrying on maternity homes in their areas are made aware of the requirements of registration.

### Correspondence.

#### WHAT IS COMPARATIVE MEDICINE?

SIR—In the report of the meeting of the Section of Comparative Medicine of the Royal Society of Medicine (BRITISH MEDICAL JOURNAL, October 29th pp 783 and 787) no actual definition of "comparative medicine" is given. As I study comparative medicine seems so extensive that it can only be defined somewhat as follows:

The study of disease and its treatment by comparison, in human beings, animals and plants and in relation to race or variety, sex, age, place in family, climate, season, soil, food and mode of life (as modified by occupation, habits and surrounding influences).

It must of course necessarily include the study of normal as well as pathological anatomy and physiology and must partially depend on a variety of other scientific knowledge.—I am, etc.

London W1 Oct 28th F PARKES WEBER

#### TUBERCULOSIS OF THE KIDNEY

SIR—I have read with great interest the account of the discussion on renal tuberculosis at the Annual Meeting held in Edinburgh last July (BRITISH MEDICAL JOURNAL, October 8th pp 625-633), and hope you will allow me to raise a few points.

Regarding Professor Fullerton's method of retroperitoneal catheterization of the ureters by open operation, I would like to mention that in 1913 and 1914 I had four cases on which I did a similar operation, but, instead of making two oblique incisions, I exposed the pelvic portions of both ureters by means of a single median incision. The badly infected ureter was recognizable at a glance. It was thick and hard and was stretched like a bowstring across the pelvis. The apparently healthy ureter was catheterized through an incision about an eighth of an inch long in its wall.

Recently I have not found it necessary to expose the ureters for the purpose of making a diagnosis as I have adopted a different method. No patient with one perfectly healthy and unobstructed kidney ever has permanently high blood urea. On the other hand, normal blood urea does not guarantee the integrity of one kidney, as it may be found where both kidneys are only slightly damaged. If, therefore, a patient suffering from advanced renal tuberculosis gives a high blood urea the disease is bilateral, and I feel that it is unnecessary to catheterize his ureters; as operation is contraindicated. If he gives a normal blood urea the ureters should be catheterized, and in most cases the disease will be found to be unilateral. In this way it is possible to weed out most of the inoperable cases without putting them to any discomfort. I have never failed to catheterize the ureters in any case with a normal blood urea, and therefore have not been driven to expose them by open operation in order to make a diagnosis.

I note that Sir John Thomson Walker stated that chromocystoscopy has little value in deciding whether the kidney is tuberculous. Strictly speaking he is correct, as a delay in the appearance of the colour or a diminution in its intensity is found in a host of conditions other than renal tuberculosis. But if tubercle bacilli have been found in the urine a poor diminution of the dye on one side is compared with the other is strong presumptive evidence of involvement of that kidney. I believe that, in order to obtain the best results from this test, only a small quantity of indigo-carmin (5 c.c. of a 0.4 per cent solution) should be injected into a vein. I never give intramuscular injections as the time of appearance of the colour is so variable (from six to ten minutes with a healthy kidney). The excretion of the dye commences four to five minutes after an intravenous injection. Again if a large quantity of the dye is injected the blue coloration is so intense that the cystoscopic medium soon becomes obscured and in addition it may be impossible to discover any difference in the intensity of the colour coming from the two ureters, although one kidney may be actually eliminating much more dye than the other. If two solutions of the dye are very dilute a slight difference in their concentration is readily recognizable by the shade, if they are both strong the colour is so intense that a considerable difference in their concentration cannot be detected by inspection. After an intravenous injection of a small quantity of indigo-carmin, not only is the first appearance of the dye easily recognized, but any difference in intensity of the colour from the two sides is usually well marked.

Of course, a good elimination of the dye does not preclude a minute tuberculous lesion of the kidney. The results of this test must always be controlled by catheterization of the ureters before operation. Chromocystoscopy is a test not of renal tuberculosis but of the functional value of the kidney. Tuberculosis rapidly destroys the kidney's excretory value and therefore this test is of definite though indirect use—I am, etc.

#### DISEMBOWELMENT AND SHOCK

SIR—I noticed in your issue of September 24th (p 569) a letter referring to the capacity of the human organism to endure the shock of being disembowelled. The following incident may be of interest.

During the war I was medical officer to the 33rd Battalion Canadians and in the battle of Givenchy the first Canadian battalion was very badly cut up, owing to the fact that one or two of the battalions of the British Division on our left met with obstacles which caused our

left flank to be in the air. On our immediate left was a Highland battalion. During this engagement a Highlander walked into my dressing station with his arms crossed in front of his abdomen. He was deathly white and sank to the floor. We placed him on a stretcher and asked him what he would like best, and he asked for a piece of bread, which was given to him. When he held up his hand to receive it, it was observed that he was holding several coils of intestines in his arms. He had been cut across the abdomen with a bullet as mortally as if it had been done with a knife. His intestines had not been perforated. He was given morphine, and dispatched as rapidly as possible to a clearing station in the rear. Unfortunately I was not able, in the heat of the moment, to follow his career.

His fortitude was typical of many of the British soldiers to whom it had been my privilege, from time to time, to render first aid—I am, etc.,

A. K. HAYWOOD, M.D.,

October 13th

Superintendent, Montreal General Hospital

\* Dr. C. E. Morris (Holywell, Flintshire) sends us a note of a tradition current in the Flintshire upland about a certain Captain Morgan, who, while on his knees, and holding up his escaping bowels in one hand, slew with his sword his three assailants.

### PYREXIA DURING THE PUERPERIUM

SIR,—I am surprised at the number of practitioners who rush into print on insufficient information. Your correspondents, regarding the above, have failed to appreciate that the Ministry did not intend the terms "puerperal fever" and "puerperal pyrexia" to be synonymous. Every case of a temperature of 100.4° for more than twenty-four hours is not notifiable as puerperal fever, nor is every woman with a headache and a temperature due to mammary irritation or constipation. The Puerperal Fever and Pyrexia Regulations state definitely that puerperal pyrexia is reserved for that class of a rise of temperature which cannot be notified as puerperal fever. The Orders relative to the above are neither unjust nor ridiculous as stated, but if, as your correspondents have deduced, fever and pyrexia are to be used as synonymous terms, then I agree with the Northumberland practitioner that this is indeed meddlesome legislation—I am, etc.,

Health Department,  
Sunderland, Oct 31st

A. STUART HEBBLETHWAITE,  
Medical Officer of Health

### PREVENTION OF MATERNAL MORTALITY

SIR,—By this time many practitioners have read the annual report issued by the Ministry of Health.

Encouraging as many of the sections are, some of them make depressing reading, and in this category is the reference to the mortality of women in childbed. The new midwifery was introduced solely with the idea of reducing mortality. It has now had at least five years' trial. During the last three the death rate, both from puerperal sepsis and from all other causes, has gone steadily up. Meanwhile the birth rate has rapidly fallen.

If these be the results of non-interference, surely it would be better to trust more to art and less to nature. Of course, in a civilized community there is no such thing as entirely natural labour, but there is "assisted" and "unassisted" labour. The latter undoubtedly involves longer suffering, and the mortality figures appear to show that it also means increased risk—I am, etc.,

A. CAMMELL STARK

Wanstead, E 12

### "THE HISTORICAL ASPECTS OF QUACKERY"

SIR,—Sir James Barr's last letter makes it very difficult for me to continue this correspondence, but Dr. Kenelm Reid seems to be under a misapprehension which I would like to remove.

In his letters Dr. Kenelm Reid has given to remarks of mine a far wider interpretation than was intended or than can correctly be read into them. The remarks in question applied only to those who "believe" that "all diseases diagnosed and treated by means of two boxes

containing some simple electrical apparatus" persons I naturally designated "the followers of Abrams" since this was the theory admittedly held and put forward by Abrams himself.

Dr. Kenelm Reid makes it perfectly clear in the first paragraph of his letter that he, and presumably all the editor of, and those who contributed anonymously to, the book *Abrams' Methods of Diagnosis and Treatment*, do come within this category, since this book, as quoted by Dr. Kenelm Reid, does not pretend to support the extravagant claims.

My remarks were not meant to apply to, and, I venture to suggest, if perused carefully could not be read as applied to, those who do not advance such claims. While I regret that my words have been misconstrued, it is obvious that a suggestion which has not been made is not capable of withdrawal—I am, etc.,

Edinburgh, Oct 31st

A. J. CLARK

### SECOND ATTACK OF PITIRIASIS ROSA

SIR,—In your issue of September 24th Dr. Gordon Edolston (p. 549) gives an interesting memorandum on a second attack of pityriasis rosea, and Dr. Graham Little in your issue of October 8th (p. 663) mentions several cases cited by Drs. Whitfield, Dore, and Gray.

One week ago a young doctor in this city consulted me. He was suffering from an attack of pityriasis rosea of three weeks' duration, the herald patch having been near the right nipple. The rash was profuse and of the macular type, and he had felt "out of sorts" for the previous three weeks. He told me that in 1917 while in the army, he had been in hospital for two weeks with a rash which had then been diagnosed as pityriasis rosea.

A curious fact in both this case and that of Dr. Edolston is the length of time between the first and second attacks—three and a half years in Dr. Edolston's case and five years in the case reported above. The well known fact that recurrences of pityriasis rosea are extremely rare leads one to think that in the above cases only temporary immunity was conferred by the first attack—I am, etc.,

IRVING H. McCRAW

Belfast Oct 25th

### "SYMPTOM-COMPLEX" OR "SYNDROME"

SIR,—What exactly is the pathogeny of the expression "symptom complex"? So far as I know it has no existence in French, being replaced by the more elegant and equivalent in English "syndrome". Is there an expressive and definite word "syndrome"? Is there a reason for the retention of this clumsy Greco-Latin hybrid in English medical literature? Its appearance in journals and textbooks—I speak from the viewpoint of the press—seems to have coincided with that of the French word in the last few years when research was distinguishing diseases as entities from mere associated groups of symptoms—the sense in which the scholarly professor of medicine at the University of Edinburgh uses it of pernicious anaemia on p. 671 of the *Journal*, October 15th, 1927.

There appear to be several objections to the use of "symptom complex". On the other hand "syndrome" from the Greek *συνδρομή*—association or group—seems sufficient for our purpose. It can be used by itself or with the name of a disease—thus the syndrome of typhoid fever meaning the group of symptoms we associate with that ailment, or we can say, with Professor Gulland, pericarditis is a syndrome rather than a disease—I am, etc.,

A. A. WATSON, M.D.

Cannes, Oct 17th

### A PROPOSED ASTHMA RESEARCH COUNCIL

SIR,—Sir James Dundas-Grant has done well to draw attention again (October 29th, p. 804) to the frequent association of nasal disease with asthma, and to the benefit which often results from the cure of the nasal disease. It is not, however, with obvious nasal disease that the omission of a rhino-scope examination is likely to be a mistake, but rather with those cases of nasal disease which have been termed latent, and especially those in which there is no nasal affection though the condition has such beneficial effects on asthma as the

has come to look upon the association of uterine disease with asthma as fortunate for the patient in that its cure is followed in most cases by great benefit to the asthmatic and frequently by disappearance of the attacks.

The relationship of the two affections is a matter for more extended discussion than is possible in a letter. Asthma is by no means always nor indeed in most instances, obvious. It must be looked for, and the only definite method of diagnosis is by examination of the contents of the cavity. Laryngeal examination and transillumination are not definite and it is because this is not sufficiently recognized that so many cases are overlooked. What is more, too—and this is of special significance in regard to asthma—uterine disease is much more common in children than is generally supposed. The signs and symptoms are masked by the presence of adenoids—I am, etc.,

Glasgow Oct. 20th.

W S SYME

### THERAPEUTIC ABORTION

Sir—Of late a new and disturbing medical term has made its appearance in increasing prominence in the columns of the *Journal*—namely, "therapeutic abortion." May I, a humble general practitioner, inquire the meaning of the term? Is it used to describe the failures of the obstetric art or is it used to cloak the criminal abortions? As I consider them induced by those leaders of the profession who profess to see in the desire of well-to-do couples to avoid parenthood sufficient mental upset to justify the destruction of an unborn, but living and viable human being?

I submit that the use of the term is unmoral and scientifically unjustifiable. It is degrading to our ancient art and it can but lead to a lowering of our professional status in the eyes of the public to see in the columns of the leading medical journal of the world discussions as to when the slaughter of an unborn child may be carried out. Abortion is never justified, even when carried out at the behest of a governing power, as in Prussia at the present day. I venture to predict that the increasing laxity in our regard of the sacredness of human life will if unchecked lead in time to discussions under the head of "therapeutic homicide."

I have waited for those of greater standing than myself in the profession to tackle this matter, but in vain. Perhaps it is fitting that the general practitioner should come forward to protect family life—I am, etc.,

London N.W.5 Oct. 19th

P P DALTON

## Universities and Colleges

### UNIVERSITY OF OXFORD

THE Vice-Chancellor announces that Sir Archibald Garrod, KCMG, MD, FRS, has tendered to the Prime Minister his resignation of the office of Regius Professor of Medicine which he has held since 1920. The resignation will take effect as from December 31st 1927.

### UNIVERSITY OF CAMBRIDGE

At a congregation held on October 25th the following medical degrees were conferred:

MD—C E Newman  
MR BChir—G B W Walker, G A Q Lennane  
BChir—E H A Walker

### ROYAL COLLEGE OF PHYSICIANS OF LONDON

An ordinary quarterly meeting of the Royal College of Physicians of London was held on October 27th when the President Sir John Rose Bradford was in the chair.

#### Members

#### Appointments

On the nomination of the Council Dr Robert Arthur Young CBE Dr Joseph Shaw Bolton Dr Grafton Elliot Smith and Sir Percy William Lawsett Smith KCB CMG were elected Council members to take the places of Dr A G Phear Sir St Clair Thom on Dr Bedford Pierce and Sir Leonard Rogers.

Sir Francis Champneys was re-elected a representative of the College on the Central Midwives Board.

Dr R A Young was reappointed a member of the Committee of Management.

#### Lectures

The President announced the appointment of Dr A G Gib on to the British Law Lectureship for 1928 and of Dr J Graham Forbes to the Midwifery Lectureship for 1929.

#### Prize

The President announced the award of the Jenks Memorial Scholarship for 1927 to James Ramsay Minthead Martu formerly of Epsom College.

The President announced that the Gilbert Blane Gold Medal had been awarded to Commander A W McKinnon MB BSc and the Weber-Pries Prize to Dr A Stauley Griffith of Cambridge.

#### Appointment of Representative

Sir E Farquhar Buzzard Senior Censor was appointed to represent the College at the centenary celebration in June 1928 of the incorporation of the Institution of Civil Engineers by Royal Charter.

The President was appointed to represent the College on the Organizing Committee of the International Congress of Military Medicine and Pharmacy to be held in London on May 6th to 11th 1929.

#### Designation of Fellowship

The designation of the Fellowship by Dr J G Taylor (Chester) was accepted with regret.

#### Diploma in Obstetrics

A communication was received from the Society of Apothecaries stating that the Society had decided to institute a Diploma in Obstetrics.

#### Diploma in Pathology

A communication from the British Pathological Association regarding the desirability of instituting a special Diploma in Pathology was referred to a committee for consideration.

#### Committee of Management

The Committee of Management recommended that the following universities be added to the list of institutions where graduates in medicine are admissible to the Final Examination in Medicine, Surgery and Midwifery under the conditions stipulated in Section III of the old regulations and paragraph in the letter III of the regulations dated January 1st 1923: Germany University of Cologne, Spain University of Barcelona, Memphis University of Tennessee College of Medicine.

The Committee reported that in accordance with the conditions laid down in April 1920 by the Royal Colleges the following recognized courses of instruction for DPH in the following institutions: Haffkine Institute Parel Bombay, London School of Hygiene

and Tropical Medicine (the five months' course recognized for the course of parasitology only), University of Lucknow

The Committee also reported the retirement of Dr R A Young C B E, and Mr F J Steward from the Committee under the conditions of paragraph vi Part I, of the scheme for constituting the Examining Board in England

#### Miscellaneous

A letter was read from Mr F G Hallett expressing his appreciation of the action of the College on his retirement from the office of Secretary to the Conjoint Board

Communications from the Royal College of Surgeons reporting the proceedings of the Council of that College were received

After some formal College business had been transacted, the President dissolved the meeting

#### Obituary.

DR FRIDRICK JOHN WILLIAM COX, who died on October 7th, at his residence in Bowdon, Cheshire, in his 70th year, was the son of the late Dr Cox of Innerleithen. He received his medical education at Edinburgh, where he obtained the diplomas L R C P, L R C S in 1880, and graduated M B in the following year, he proceeded M D in 1893. After practising at Eccles for some years with his brother he went to Bowdon in 1897. He held the appointments of senior surgeon to the Manchester Ear Hospital, and consulting rural surgeon to the Buxton Cottage Hospital, the Altrincham General Hospital, and the Manchester Warehousemen and Clerks' Association. Dr Cox was a member of the Edinburgh Royal Medical Society and the Manchester Medical, Pathological, and Clinical Society. He took an active interest in the British Medical Association, and in 1902 was vice-president of the Section of Otolaryngology at the Annual Meeting at Manchester. He was a member of the executive committee of the Altrincham Division in 1904 and 1910, vice-chairman of the Division from 1907 to 1908, and chairman in 1909. He was also a member of the executive committee of the Mid-Cheshire Division in 1915.

DR HENRY WILLIAM EVANS, who died on October 25th, at the age of 37, received his medical education at Guy's Hospital, and obtained the diplomas M R C S, L R C P in 1913, in the following year he graduated M B, B S Lond, and proceeded M D in 1920. At the outbreak of war he received a commission in the R A M C and went to France in 1915. While on the Somme he was isolated with his ambulance company for two days, he continued his work under extremely difficult conditions until relief came, and for this he was awarded the Military Cross. He was invalided home in 1917, but went out to Egypt and Palestine in 1918, and took part in Allenby's capture of Jerusalem, where he remained until December of the following year. He returned to Guy's Hospital in 1920, and was appointed resident obstetrician to Mr Bellingham Smith. In 1921 he married and settled at Reedham in Norfolk, becoming eventually a partner with Dr Eliot Blake, he removed to Brundall in 1923. Throughout his life he took great interest in sport, and at Bedford Modern School he was in the first rowing four, a member of the first fifteen, and won the school cup for running. On leaving school he played for the East Midlands fifteen, and at Guy's Hospital joined the Artists' Volunteer Corps and won the Territorial championship for running. He was chosen to represent the British Isles at the Stockholm Olympic Games, but was unable to spare the time for this. A colleague writes: "It is difficult to express in words the rare qualities which Henry Evans possessed. In his work he was not only brilliant, he was essentially sound. He was a man of wide interests, and took ever more pleasure in literature than in sport, in which he excelled. He was gifted with sympathy tempered by a keen sense of humour, and with emotions controlled by sound judgement. He was deeply loved by all who knew him, and won the affection and confidence of his many patients, rich and poor alike. He leaves a widow with two young children."

#### Medical News.

UNDER the auspices of the Health Organization of the League of Nations an international continuation course in public health commenced at the house of the Society of Medical Officers of Health, 1, Upper Montague Street, W.C.1, on November 3rd, and will continue until December 1st. The opening address is being delivered to-day (Friday, November 4th) by Sir George Newman, on the development of public health administration and practice in England. The lecturers include Dr Foranelli, deputy director of the Federal Public Health Services, Austria, Colonel L. W. Harrison, Professor B. Nocht of Hamburg, Dr I. J. H. Conits, Sir Henry Gauvain, Dr F. E. Tremante, M.P., Professor G. Y. Giglioli, lecturer on industrial hygiene, Florence, Dr A. W. J. MacFadden, Dr Charles Porter, Professor F. Neufeld of Berlin, Professor C. Parquet of Vienna, and Dr W. M. Willoughby. A few tickets for the course are available for medical officers of health, and may be obtained from the executive secretary, 1, Upper Montague Street, W.C.1.

SIR STCLAIR THOMSON will deliver a lecture for the Fellowship of Medicine on bleeding from the nose and throat at the Medical Society, 11, Chandos Street, Cavendish Square, on November 7th, at 5 p.m. There will be demonstrations on November 9th by Mr. Greeves at the Royal London Ophthalmic Hospital at midday, and by Sir William Wilcock at St. Mary's Hospital at 3 p.m., another demonstration will be given at the Cancer Hospital on November 10th, at 3 p.m., by Mr. Cecil Rowntree. The lecture and the demonstrations are free to medical practitioners. From November 14th to 26th St. Peter's Hospital will hold a special course consisting of clinical instruction, cystoscopes, and lectures on diseases of the urinary tract. A three-week course in medicine, surgery, and gynaecology, occupying the mornings and some afternoons, will begin on November 14th at the Royal Waterloo Hospital. A series of clinical demonstrations upon selected cases will be given daily at the West End Hospital for Nervous Diseases, at 5 p.m., from November 21st until December 17th. A special course for the general practitioner will be held at the London Temperance Hospital from November 21st to December 3rd, at 4.30 to 6 p.m. every afternoon. At St. Mark's Hospital there will be a week's special course in proctology from November 28th to December 3rd. Copies of syllabuses and of the *Post Graduate Medical Journal* may be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

THE annual address arranged by the medical staff of the Central London Throat, Nose, and Ear Hospital, Gray's Inn Road, W.C., will be given on Friday next, November 11th, at 4 o'clock, by Mr. Ernest B. Waggott. The title of the address is "On Observation."

AT the next meeting of the Optical Society to be held at the Imperial College of Science on Thursday, November 10th, at 7.30 p.m., a communication on the resolution of gratings by the astigmatic eye will be made by Messrs J. R. Hamblin and T. H. Winslet, and Mr. O. Aves will discuss the design and trial frame.

THE Medical Officers of Schools Association will hold a general meeting at the house of the Medical Society of London (11, Chandos Street, Cavendish Square, W.1) on Friday next, at 5 p.m., when Mr. W. Rowley Bristol, F.R.C.S., orthopaedic surgeon to St. Thomas's Hospital will read a paper on the commoner disabilities of bones and joints in adolescence.

FOUR lectures on insanity and the history of its treatment will be given by Sir Robert Armstrong Jones, C.B.E., M.D., at Gresham College, Baslinghall Street, London, E.C.2, on November 7th, 8th, 10th, and 11th, the first will deal with the nature of insanity, the second will be an historical survey, and in the third the report of the Royal Commission will be discussed. The last lecture will be illustrated by lantern slides of old and new treatment. The lectures will be given at 6 p.m. on each day and are open free to all.

THE annual dinner of the Royal Society of Medicine will be held at the Hotel Victoria, Northumberland Avenue, W.C.2, on Wednesday, November 16th, at 7.30 p.m. Lord Darling is to be the society's guest of honour.

THE fifty-first anniversary dinner of the Central Graduate's Club of St. Bartholomew's Hospital will take place on Wednesday, November 23rd, at 7.30 p.m., in the Hotel Victoria (Oak Room), with Dr. John F. Morris in the chair. The honorary secretaries are Dr. Henry J. Morris and Mr. Reginald Vici. Price of dinner 12s. 6d., exclusive of wines.

THE Sheffield medical dinner will be held at the Grand Hotel Sheffield on Thursday November 10th at 7.45 p.m., when Professor A. J. Hall will preside. Professor H. R. Dean of Cambridge will respond to the toast of The Medical Profession. There will be musical items during the evening. Applications for tickets (12s 6d, exclusive of wines) should be made by November 8th to the honorary secretary, Dr Plesance 2 Ormeau Road Fulwood Sheffield.

THE annual dinner of the Renouveau Association of the Prince of Wales's Hospital Tottenham, N. will be held at the Trocadero Restaurant Piccadilly Circus W. on Friday, November 11th at 8.15 p.m. The chair will be occupied by Mr. Edward Gillespie. The price of the dinner will be 12s 6d (exclusive of wines) for members and their guests. The secretary is Dr J. Browning Alexander, 42 Harley Street W. 1.

THE annual dinner of the Society of Medical Officers of Health will take place at the Piccadilly Hotel, London, W., on Thursday November 17th. The president, Dr James Whetley, will take the chair at 7.30 p.m. The society has arranged to hold five general discussions during the present session. On November 18th the subject for discussion will be health aspects of the Factories Bill. On December 16th health aspects of the Poor Law reform proposals. On January 20th recent advances in the knowledge of food and on February 17th the control of smallpox. These meetings will all be held at 5 o'clock at the house of the society, 1 Upper Montague Street Russell Square W.C. On April 23rd the society will meet at Bath and a discussion will take place at 3 o'clock on the causes of the decline in tuberculosis mortality. The first of the four opening speakers being Sir Robert Philip, President of the British Medical Association.

THE medical staff of the Royal Dental Hospital, Leicester Square W.C. will be at home on Saturday afternoon, November 25th, when the hospital will be open for inspection and courses of interest shown. The dinner of past and present students of the hospital will take place the same evening at the Trocadero Restaurant, Shaftesbury Avenue, at 7 o'clock, under the presidency of Mr J. S. Amore.

DR C. S. MEERS F.R.S. will take the chair at a discussion organized by the British Institute of Philosophical Studies when the question whether the new psychology is a department of education or of medicine will be opened by Dr H. Crichton Miller and Mr. Kenneth Pichmond. It will take place on Tuesday next at 8.15 p.m. at the Royal Society of Arts, 18 John Street, Adelphi W.C. 2.

THE third annual Norman Lockyer Lecture of the British Science Guild will be given by Dean Inge on Monday, November 21st, at 4 p.m. in the Goldsmiths Hall, Foster Lane E.C. when the president of the Guild, the Right Hon. Sir Alfred Mond Bt. M.P. will be in the chair. The subject of the lecture will be scientific ethics. Admission is free and tickets may be obtained from the secretary of the Guild, 6 John Street, Adelphi W.C. 2.

THE educative value of E. F. Harrison's work in pharmacy will be the subject of an address given by Mr E. Saville Peck M.A. at the first evening meeting of the Pharmaceutical Society of Great Britain which will take place on Tuesday next at 8 p.m. Afterwards Harrison's lectureship medals will be presented to the lecturer and to Mr F. H. Carr, C.B.E. F.R.C.I. who will be remembered that Harrison was for many years pharmaceutical adviser to the BRITISH MEDICAL JOURNAL and wrote the books *Secret Remedies* and *More Secret Remedies*.

SIR JOHN ROBERTSON who recently retired from the office of medical officer of health for Birmingham has been presented by the principal officers of the Birmingham Corporation with a set of 10 English cent glassware. He was also presented at a meeting of past and present members of the Birmingham Public Health Committee on October 23rd with a silver tea service, a copy of Groves's *Dictionary of Music and Musicians* and an illuminated engrossment of the resolution adopted by the Health Committee on September 23rd.

DR CHARLES EDWARDS J.P. of Andover has accepted the invitation of the Aldermen's Committee to be nominated as mayor. At his election on the council three years ago he headed the poll and his work on it has won general approbation. Dr Edwards received his medical education at Guy's Hospital and in 1900 obtained the diploma of M.R.C.S., L.R.C.P. He graduated M.D. Durham in 1920. He is surgeon to the Andover Hospital and is an honorary licentiate member of the St. John Ambulance Association. He is a representative of the Winchester Division on the Southern Branch Council of the British Medical Association.

DR JOHN PRIESTLEY who has already announced, is retiring from the post of medical officer of health for Lambeth after thirty-two years' service, has been presented by the local members of the medical profession with an inscribed silver salver. In making the presentation at a meeting at

the Lambeth Town Hall on October 27th the mayor, Dr R. S. Pearson, said that Dr Priestley during his term of office had succeeded in making Lambeth one of the healthiest boroughs of the kingdom. The other speakers included Dr F. N. Kay Menzies, Dr Harvey Norton, and Dr V. G. Fenton.

DR E. A. GREGG, J.P. ex Mayor of St. Pancras has been presented by his colleagues on the borough council with his portrait while Mrs. Gregg was the recipient of a small mirror or ear. In making the presentation Alderman Collins acknowledged the strict impartiality with which Alderman Gregg had carried out his duties whilst mayor and had proved himself to be a man of outstanding personality.

DR GEORGE ROBERT BRUCE (M.O.H. Hastings) has been elected a Fellow of the Royal Sanitary Institute.

THE anonymous donor who gave £750 in response to the Lord Mayor's appeal at the opening ceremony of the New Wing of St. Mary's Hospital, City Road on October 26th to complete the sum of £3,000, which is the estimated cost of the building, was Mr H. Clifford Turner. This is Mr Clifford Turner's third generous donation to the funds of this hospital.

THE Critchfield House convalescent home at Brighton is established on a small estate bequeathed for the purpose by Miss Rose Greene. It is intended for gentlewomen of limited means, especially those leaving hospital after an operation or acute illness, so as to give them an opportunity of completing their convalescence before resuming their active duties in life. It is open to persons of all religious denominations. It can accommodate seven patients, and is conducted on the lines of a first-rate nursing home with as few rules as possible so that the inmates may feel at home. As the endowment is not sufficiently large to pay the whole outlay a charge of 30s. to £2 a week is made but medical attendance when necessary and medicine are provided free of charge. The institution is managed by a committee which meets weekly and we are indebted to Dr C. Percival White, a member of the House Committee for these particulars. There is a resident trained matron and nurse. Persons merely requiring a holiday, and cases of phthisis, acute cancer, infectious diseases, mental trouble and the drug habit, are not admitted. The home has been open for two years but it appears to be insufficiently known as the number of applications received is not sufficient to keep it always full. Information can be obtained from the Matron, Critchfield House, 5 Ilwood Road, Brighton.

THE ninth annual report of the Bedford Comitee Catholic Mental Welfare Hospital for Children for the year 1926-27 has just been issued. It has a prefatory note by the Archbishop of Birmingham and contains an interesting account of the methods and aims of this institution written by the administrator and superintendent the Rt. Rev. Monsignor Newsome who discusses the mental deficiency problem in the light of Roman Catholic philosophy. The hospital is situated at Defford near Worcester. It was first opened for the reception of patients on October 1st 1917. The report is fully illustrated and contains an appendix from the research department describing an investigation into the correlations of "mental ages" with manual, social, and industrial abilities.

THE eighth annual report of the Walter and Eliza Hall Institute of Research in Pathology and Medicine at Melbourne covers the year ending June 30th 1927 during which a book on hydatid disease has been completed for publication, and a study of pancreatic regeneration concluded. Further work on streptococcal strains is in progress and a preliminary study has been made of the organism's concern in puerperal sepsis. An experimental investigation has been continued with a view to determining whether there is any relation between cancer and tuberculosis. Other subjects under consideration include the pathological histology of the dental tissues, the mechanism of compensatory renal hypertrophy, and sarcoma of the testis.

AN attractive advertisement of Egypt and the Sudan has been issued by the Tourist Development Association of Egypt. The cover of the book shows a design from one of the panels in the vaulted chamber created by Thutmose III to the goddess Hathor. The book contains a series of articles on the sights, scenery, and mystery of Egypt which are interesting and readable. It is profusely illustrated with photographs, and should be quite useful in furthering the objects of the association. The book is obtainable from Messrs. Selig, Ltd., 163 and 167 Fleet Street E.C. 4.

PROFESSOR EMIL ABDEPHAUDE of Halle and Professor Max Nonne of Hamburg have been nominated honorary members of the Royal Academy of Medicine at Rome.

DR PAUL DELEEN of Liege has been nominated president of the Belgian Society of Otorhinolaryngology.

THE State vaccination institute of Berlin has recently celebrated the 125th anniversary of its foundation.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

**ORIGINAL ARTICLES** and **LETTERS** forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are

**EDITOR** of the **BRITISH MEDICAL JOURNAL**, *Antiology Westcent, London*

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), *Articulate Westcent, London*

**MEDICAL SECRETARY** *Mediscera Westcent London*

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams *Racillus, Dublin* telephone 4737 Dublin), and of the Scottish Office, 6 Drumshough Gardens Edinburgh (telegrams *Associate, Edinburgh*, telephone 24361 Edinburgh).

### QUERIES AND ANSWERS

"**OBSTRUCTION**," who contemplates having a colostomy performed, would like to have the experiences of some medical man who has undergone this operation especially as to the amount of disagreeableness thereby entailed and the amount of time spent daily in dressing the wound. Is the mental picture that every medical man has of this condition an exaggerated one?

#### SPA TREATMENT

"**R.P.S.**" asks for information about the baths at Jura in Peru, said to be efficacious in gout.

**SURGON CAPTAIN E. H. MIDLIN, R.N. (ret.)** asks for advice in the choice of a spa for the treatment of chronic uticular rheumatism and fibrosis, with a certain degree of arterio sclerosis. He has thought of Dordrecht or Bath.

#### BORING THE LOBBLE

**DR. JAMES BROWN** (Stuckley, Birmingham), sends us a sketch (reproduced herewith) of an instrument which is used by jewellers to puncture the lobule of the ear. A is a trocar and cannula, B is a trigger, C a pull back to set the apparatus, and D a hinge, when set, the trocar and cannula are withdrawn into the tube. "I have used this instrument several times," Dr. Brown adds, "the 'operation' can be done quickly and accurately and is practically painless. The cost of the

Instrument is about 10s 6d, it can be obtained from the Wilmot Manufacturing Company, Camden Street, Birmingham."

#### STOMACH COUGH

"**M.B. CANTAB**" asks for help in self treatment. He has suffered for years from persistent night cough, the performance being always the same, waking from 1 to 2 a.m.—that is roughly five hours after last meal—with violent irritation in the throat, coughing incessantly for about half an hour or more until flatulencies in the stomach and can be expelled, when the irritation ceases and rest can be resumed. Condition diagnosed by phys. clin. as nervous hyperchlorhydria, but treatment by dieting and various stomach mixtures has been unsuccessful. Bromides occasionally relieve, but are undependable. Alkalies taken at the time shorten the attack and hasten expulsion of flatulencies but taken at bedtime seem powerless to ward off the attacks, which have persisted for some ten years. Teeth good, throat normal, general health good, and no conscious indigestion by day.

#### INCOME TAX

##### Free Quarters

"**P.E.A.**" holds an appointment as assistant medical officer to a convalescent home at a salary plus free quarters and board in the home. Are his free quarters assessable to income tax?

It seems that the authorities recognize that the home is entitled to exemption from tax, Schedule A but there is a

statutory qualification to such exemptions—"or for as is occupied by any individual officer whose total annual income amounts to £150." Although "I.L.A." has the free quarters of the statutory occupier of the premises as a whole, the authority administering the home, and the return of the value of the quarters as liable to tax should therefore be of a restriction of the exemption granted to the authorities in other words, the tax is payable, but by the treasurer rather than by our correspondent.

#### Cash Basis

"**A.W.S.O.**" has been assessed for the past twenty years on a cash receipt basis. He has now been asked, through the assessor by whom his returns are lodged, to revise his figures so as to show them on the basis of "fees earned." For various reasons this would prove very troublesome.

Unless the practice is expanding there would apparently be no ground for believing that a revision to the value of fees earned would effect any material change over a period of twenty years and in such circumstances it is understood that inspectors of taxes do not press for the change to be made. We suggest that our correspondent should communicate with the inspector—or preferably see him if practicable—and explain the particular difficulties in meeting his request, including that of the specific valuation of outstanding debts, and endeavour to show him that compliance is unnecessary. Theoretically the inspector is right but on the assumption made above his request is not in accordance with the normal practice, and would not, we believe, be supported on appeal to the Commissioners appointed to hear appeals against assessments. In any case insistence on the request would have to be backed by a previous amendment of the existing assessment, which apparently agrees with the cash basis return.

### LETTERS NOTES ETC

#### THE REGISTRATION OF NURSING HOMES

**MISS L. RAMSON**, President of the Incorporated Midwives' Institute, writes: We feel that your readers are not sufficiently aware of the dangerous provisions that have been inserted in the Nursing Homes (Registration) Bill. These place the duty of inspecting nursing and maternity homes in the hands of the smaller local authorities (in many cases the rural or district councils) and propose the repeal of Part II of the Midwives and Maternity Homes Act 1926. This Act, which has been in force satisfactorily since passed, placed the inspection of maternity homes under the same authority as the midwives—the county councils and the county borough councils. If the new bill is amended as passed, the result will be dual inspection of the home being under one authority and the midwives working in it under another, with conflicting rules and regulations, the possibility of undesirable administrative work, of the influence of personal friends and vested interests, and the certainty that the smaller authorities would not be able to provide well trained, whole time inspectors with expert knowledge.

#### MINISTRUAL "U. CHIANINNESS"

**COLONEL P. BLOOMER GHIS** (Tollington) writes: Whilst I do not believe that the usual brief handling of food by a menstruating woman will decompose the food, I know by actual experience that the prolonged contact between the hands of a menstruating woman in the process of rubbing salt, etc., for the preservation of hams will produce a decomposition and render the hams uneatable. This fact is well known to the farmers who live in Herefordshire, Radnorshire, and Breconshire.

#### SOY BEAN FEEDS AS CULTIVATED MEDIUM

**MAJOR H. ST. ANNAUD AGATE** (Salisbury) writes: In the **BRITISH MEDICAL JOURNAL** of October 22nd (Hygiene para 379) there appears an extract from the *Lancet* dated 1st June 1927 under the heading of "Soy bean seed as a culture medium," by L. Vitale. I should like to point out that in my original communication entitled "The standardization of a culture medium" published in the *Journal of the I.C.C.*, dated March 1922 I mentioned soy beans as being among the substances used in the preparation of culture medium. I have used it, with the addition of 0.5 per cent of marmite. I have used this for about eight years with uniformly satisfactory results. I can, therefore, confirm L. Vitale's experience.

#### A CORRECTED PRICE

The price of *The Inert and Its Social Adjustment* which was reviewed last week, is, we are informed, 5s. and not 3s. 6d.

#### VACANCIES

NOTIFICATIONS of offices vacant in universities, medical schools, and of vacant resident and other appointments (as published in the *Supplement* at pages 51, 52, 53, 54, and 55) will be found at pages 50, 51, 52, 53, 54, and 55 of the *Supplement* columns, and advertisements as to participating in the columns, and advertisements at pages 54 and 55. A short summary of vacant posts will be found in the *Supplement* at page 51. Columns appears in the *Supplement* at page 51.

## The FitzPatrick Lectures

ON

THE HISTORY OF BRITISH MIDWIFERY  
(1650-1800)DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS  
OF LONDON

BY

HERBERT R. SPENCER, M.D., F.R.C.P.,

EMERITUS PROFESSOR OF OBSTETRIC MEDICINE, UNIVERSITY COLLEGE  
LONDON

DR. HERBERT SPENCER said that he had chosen the subject of "The history of British midwifery from 1650 to 1800," partly for the personal reason that it was one in which he was interested and partly for the patriotic reason that it had been neglected by British writers. While admirable general histories of midwifery had been published by foreign writers and exhaustive memoirs of individual British obstetricians had been produced, no detailed account of the work of British obstetricians of the period had hitherto appeared by a British author. The lectures were an attempt to remedy the deficiency.

British midwifery at the commencement of the period was not in a satisfactory condition. It was conducted mainly by women of whom many were without the education, knowledge or character requisite for its proper practice and who maintained a determined opposition to male practitioners. The opposition was to some extent justifiable inasmuch as in the earlier part of the period male practitioners made use of destructive instruments only and had little experience of normal labour. The position of the male practitioner was long that of a consultant, as the birth of George IV. for example, the Queen was attended by Mrs. Draper while William Hunter remained in waiting in case his help should be required to deal with complications. The position began to change after the introduction of the forceps, which were coming into general use by the year 1733; the practice of midwifery was then rapidly taken up by male practitioners under the titles of men midwives, midmen or androboe hogynists. The opposition of the midwives during the transition period was naturally great and according to the fashion of the time, accompanied by much poisonous abuse exemplified by such phrases as "great-horse-god mother of a be-midwife"—the shaft levelled at Smellie by Mrs. Nibell. But by the end of the century the new situation was accepted and the opposition had died down.

*The Anatomy and Physiology of Pregnancy and Labour*

The first original work on midwifery published by an Englishman was the chapter "De partu" in Harvey's *De Generatione Animalium* (1651), the English edition of which appeared in 1653—a work that justifies Aveling's description of Harvey as the Father of British Midwifery. The scientific part of Harvey's work consists in criticism based on his own observation and experiments of previous opinions concerning the anatomy and physiology of the foetus; the practical part gives evidence of extensive personal experience and is in the main devoted to the recommendation of patient watchfulness and gentleness, in ordinary cases imitating Nature and in difficult cases, "where there is necessity for handiwork in the business," employing podalic version. Harvey was held in high esteem as an obstetric physician in his day, and it was he who introduced into British obstetric medicine the wide view, the scientific spirit and the conservative practice which have been its characteristics. His death occurred on June 3rd 1657 and his body, "lipped in lead" and enclosed in the marble sarcophagus provided by the Royal College of Physicians, rests in the parish church of Hempstead in Essex.

In the study of the anatomy of the pelvis, pregnant uterus and foetus the British obstetricians of the eighteenth century took a leading place, and the illustrated

works of Hunter, Smellie and Denman have not been surpassed by their successors. William Hunter, brother of John Hunter the celebrated anatomist, was born in 1718 at Long Calderwood, Lanark. His most valued contributions to obstetrics are anatomical, and he did a great service by insisting on the importance of morbid anatomy. His great work on the gravid uterus, the outcome of the examination of the bodies of pregnant women extending over twenty-four years, is the finest of the kind and is illustrated with plates worthy to rank with those of Albinus. In addition to illustrations of the foetus, it contains dissections of the musculature of the uterus and illustrations of the decidua. Hunter was the first to describe the decidua reflexa and to show that the decidua was the lining of the uterus and was not derived from the ovum. He also gave a description of the retroverted gravid uterus and of the symphysis pubis in pregnant women, and claimed the discovery of the placental circulation, a claim also made by his brother John, and the cause of the estrangement between the two which lasted till Hunter's death in 1783. As a practitioner his place is a modest one. He carried conservative treatment to a harmful extent and failed to appreciate the value of the forceps, thinking it "a thousand pities it was ever invented, while others were using them at the time with success. He was a great perhaps the greatest anatomical teacher and his large and remunerative practice provided him with funds for the promotion of his anatomical studies and teaching which were the chief interest of his busy life and to found the Windmill Street School of Anatomy, which he built and endowed. Hunter was buried in St. James's Church, Westminster, and left the use of his museum to Matthew Baillie with reversion to the University of Glasgow where it is now preserved.

The credit of laying the foundations for the study of the mechanism of labour belongs to Sir Fielding Ould, born in Glasgow in 1710, appointed Master of the Rotunda Hospital in 1759, and author of a *Treatise of Midwifery* (1742) which shows a distinct advance on the original obstetrical books which had previously appeared in English. He made a great advance in treating labour as a mechanical process and in pointing out that the position of the foetal head at the brim and the movements of the foetus were due to the elliptical shape of the pelvis and of the shoulders and head of the foetus. He also clearly recognized for the first time that the head rotated and did not during its passage, have its long axis at right angles to that of the shoulders, but turned its chin towards one shoulder.

Ould was followed in the same line of thought by Smellie whose work forms the basis of our knowledge of the mechanism of labour. Smellie endeavoured to reduce the art of midwifery to the principles of mechanism, ascertained the make, shape and situation of the pelvis together with the form and dimensions of the child's head, and explained the method of extraction from the rules of moving bodies in different directions. He studied labour in contracted pelvis and gives an admirable description and illustration of the rachitic pelvis. He also published a case of generally contracted pelvis associated with short stature and of a pseudo-osteomalacic rachitic pelvis and he recognized the transverse contraction of the pelvic outlet in a case where "the lower end of the os ossa ischia were scarce three inches asunder." He gives measurements of the pelvis and was the first to measure the diagonal conjugate and showed that the greatest diameter at the brim was the transverse. The measurement of the true conjugate we owe to Wallace Johnson, a pupil of Smellie's. Smellie made important improvements in forceps: devised the scissors-perforator and the curved and double articulated crochets; discovered the rotation of the head in occipito-posterior positions by means of his forceps, was the first to apply the forceps to deliver the after-coming head in breech presentations and showed that the difficulty in contracted pelvis occurs at the brim and that in these cases the head usually lies with its long axis in the transverse diameter, with the sacrum deeply placed. Smellie's literary fame rests on his two great works: 1. *Treatise on the Theory and Practice of Midwifery* and 2. *Set of Anatomical Tables*. The plates in the latter work show the pelvis, external genitalia, the pregnant uterus at various months with its

Abstract of two lectures given on November 21 and 28th. The full text will be published shortly in a volume by Messrs. John Ball, Son and Daniel, Ltd.

contents, twins, the process of normal labour with illustrations of various positions of the head, the application of the forceps in head and breech delivery, the head impacted in the pelvis, with overlapping cranial bones, breech presentations, the application of forceps to the after-coming head, the head left *in utero*, and instruments with their mode of application. These plates are superior to any that had hitherto appeared, and Michaelis, the classical writer on the "narrow pelvis," says "they have perhaps achieved more in the spread of correct ideas of labour than all the books which have ever been written on the subject." William Smellie—the Master of British Midwifery—whom Fashender in his *Geschichte der Geburtshilfe* styles "one of the most important obstetricians of all times and countries," was born at Lunenburg in 1697. He studied medicine at Glasgow and began to practise in Lunenburg in 1720. In 1735 he first learnt of the existence of the forceps, and, recognizing the importance of the instrument, in 1738 moved to London, strived to teach midwifery there, and soon achieved great success both as a teacher and practitioner. In 1759 he returned to his native country, and spent the remainder of his life on his property at "Smellom" in preparing notes of his cases for publication, in which work he was aided by the literary ability of Tobias Smollett. He died in 1763, and was buried in the cemetery of St. Kentigerna, Lunenburg.

#### The Management of Pregnancy and Normal Labour

The importance of pre-maternity care of the pregnant woman was recognized in 1724 by Maubray, who gave it as one of the duties of the man-midwife or midwife-boethogynist to watch the patient during pregnancy so as to prevent all "preternatural disorders," and throughout the eighteenth century particular attention was paid to diet, hygiene, and evacuations of the patient. John Maubray is worthy of remembrance as the first teacher of practical midwifery and the first to suggest the building of a lying-in hospital in this country. He was the author of two books, *The Female Physician*, containing all the diseases incident to that sex, in virgins, wives and widows, to which is added, *The whole Art of New improved Midwifery*, published in 1724, and *Midwifery brought to Perfection by Manual Operation*, published in 1725, in which he appears as a teacher of theoretical and practical midwifery to students, and appealed for the building of a hospital for lying-in women now more than two hundred years ago. His first book met with a "very kind reception," and is, in fact, both learned and entertaining. It is in this work, in the chapter on "deformed conceptions," that the remarkable description of the "sucker" occurs, which he had seen issue from the womb of a woman whom he was attending in labour on a vessel in the Zuyder Zee. The creature was stated to be so common amongst the seafaring people as that scarce one in three escaped this strange birth. It is described as being "likest of anything in shape and size to a Moorhound, having a hooked snout, fiery sparkling eyes, a long round neck, an uncounted short tail and an extraordinary agility of feet." In its cries and noises it had somewhat the semblance of a demon, "which indeed," says Maubray, "I took it for the first time I saw it, and that none of the better sort." There is no documentary evidence that Maubray was other than an abstemious man, and the explanation of the phenomenon remains obscure. His unrelenting efforts to establish a lying-in hospital never reached fruition, the project met with opposition, the fate of so many new undertakings. But his educational scheme was an entire success. His object was to give students the opportunity of obtaining their obstetrical knowledge in this country, instead of resorting to the barber-surgeons of Paris. He arranged to give two courses of twenty lessons each, which he considered sufficient to qualify any serious student, and, further made provision, at great expense to himself, of a sufficient number of pregnant women, upon whom the students might practise the touch and perform deliveries, everyone in his turn. In this way he flattered himself that in time he would stock not only London, but the whole of Great Britain, with a set of as good expert practitioners of midwifery as any other country whatsoever could boast of. John Maubray died in 1732, "justly esteemed as an honest public-spirited man."

Sir Richard Manningham (1690-1759) who examined Mary Tofts, the "rabbit breeder" at established the first British lying-in wards in 1733.

As to the management of normal labour, the room of the period was hot, crowded, and all around the bed surrounded by heavy curtains in accordance with the universal custom of the time and the patients freely supplied with alcohol. It was only toward the middle of the century that midwives were persuaded, mainly due to the influence of Charles White and Leake, to abandon and omit the alcohol. Charles White was the author of an important *Treatise on the Management of Pregnancy and Lying-in Women*, in which full and judicious instructions for the hygiene of pregnant and parturient women are given. White states that, by attention to the proper management, out of the whole number of patients who had delivered he had never lost one by "the puerperal fever, low nervous, putrid malignant, or milk fever." He was a Manchester man, born in 1728, in the year 1767 he founded the Manchester Infirmary, where he held the position of chief surgeon for thirty-eight years. On the resignation of the post, owing to a disagreement with the management, he took a leading part in founding a "hospital in charity for attendance upon poor married women in their own homes," which developed into the St. Mary's Hospital, Manchester.

John Leake (1729-92) founded the New Westminster Lying-in Hospital in 1767. A severe and very fatal epidemic puerperal fever which occurred in that hospital was the occasion of his making a close study of the disease. He published notes of all the cases and of several of the post-mortem examinations. He opposed the view, then generally held, that the exudate on the intestines consisted of corrupted milk, and considered it to be "pure matter due to inflammation of the uterus." "The disease," he says, "truly inflammatory in the beginning, may be putrid by absorption of the purulent fluid which, if old leaven, will taint the blood." He held that the second and third were concerned in the causation, and recommended that hospital beds should not be too numerous, that special delivery beds should be instituted, the wards well ventilated, and the patient supplied with clean linen, further that disinfection should be carried out by such means as the smoke of burning wood, brimstone strewn on the floor, and whitewashing. Leake was buried in the north cloister of Westminster Abbey.

In Harvey's time patients were delivered on the "three-legged stool," but in the eighteenth century the patient delivered as a rule on the bed. The left lateral position, that usually adopted, although in special cases the patient was placed in the dorsal, reclining, sitting, or in the knee position, the last was often adopted in cases of severe labour, and, at times, for the application of the forceps. A change for the better occurred in the conduct of labour when men midwives came into practice. It had invigorated against the "sunder and more giddy" officious midwives who, lest they should become unpopular at their trade, do mightily lecture themselves and their friends the exclusive frenzy by medicinal potions, and Harvey's friend Willoughby complained of the "horrible stretchings" with which the midwives tormented their patients.

An important contribution to the management of labour was made by John Harvey in his recommendations of abdominal manipulation and pressure for the delivery after the afterbirth. His directions are given in a treatise on the preservation of the perineum and the delivery of the placenta, in which he says:

"As soon as the child is committed to the care of the accoucheur apply his hand to the belly which it will feel the contracting uterus. Then lay the flat of his hand over it, let him be a light touch, and bring it downwards or towards the pubis, and the uterus sensibly contracting and often will be of the size as to be certain that the placenta is expelled. The method we will seldom have any long to do, and help it through the external orifice, which much remains to be done."

Harvey was a teacher of midwifery at Westminster with Smellie, whom he succeeded. It was especially Harvey's advocacy of patience in the conduct of normal labour, and his

of nature, which, followed by successive teachers—Smellie, Hunter, Denman—formed the guiding spirit of British practice for the next century and a half, and it was that conservative practice which impressed the great Viennese obstetrician, Boer, who, having studied abroad, came over to England and “learned in France what Art, in England what Nature, could do.” He introduced the English practice into the great lying-in hospital of Vienna, which became under his mastership the greatest lying-in institution in Europe. From 1784 to 1822, during the last thirty-three years of which Boer was at its head, the mortality from puerperal fever was 125 per cent. Under his successor the mortality rose in the maternity ward, where medical students were admitted, to 99 per cent, whereas in the wards attended by midwives (who did not practise dissection) the mortality sank from 55 per cent to 33 per cent. It was this great difference which led Semmelweis (in 1842) to attribute puerperal fever to “putrefying animal substances” from without, and to order that the attendants should wash their hands with a solution of chloride of lime before attending midwives cases.

### Cesarean

Cesarean version was not much in favour with British obstetricians. Smellie abandoned it in favour of podalic version, which then became the favourite method of delivery in difficult cases. He was the first to apply the forceps to the after-coming head and is also sometimes credited with being the first to deliver by what is described as the Mauriceau-Smellie-Veit method but which would be more correctly called Giffard's method, since it was he who invented it. Giffard (a man midwife and surgeon who died in 1731) was the author of a work entitled *Cases in Midwifery* in which are given short accounts of 225 mostly difficult or dangerous cases attended by himself. He describes the manoeuvre thus:

I clapped one hand flat upon the breast and with the other taking hold above the shoulders drew towards me but the head did not readily follow. I therefore passed my fingers up to the child's mouth supporting the breast with my wrist and arm and putting one finger in the mouth and two others upon the cheeks. I pulled towards me and at the same time drawing with my other hand above the shoulders brought out the head.

Internal version was the operation usually performed. Bimanual version was performed by Pugh (1754); external version had not yet appeared in British practice.

### Forceps

The forceps were invented by a member of the Chamberlen family, probably by Peter Chamberlen the elder of that name—a barber-surgeon distinguished obstetric practitioner and physician to the Court, who died in 1631. The invention brought great credit to the Chamberlens, who were a family of obstetricians, and considered themselves justified in keeping it a secret for their own pecuniary advantage. The actual instruments used by them were discovered in 1813 in a secret space under the floor of a closet in Woodham Mortimer Hall, near Malden in Essex, formerly the residence of Dr. Peter Chamberlen, nephew of Peter the elder, they are now preserved in the library of the Royal Society of Medicine. Details of the invention, however, became known long before that date and the merit of first publishing an account of the forceps belongs to Edmund Chapman, a surgeon and man-midwife who was in practice for several years at South Halstead in Essex before settling in London, where he became the second public teacher of midwifery. The account appeared in his *Essay for the Improvement of Midwifery* (1733) and two years later a second edition of the *Essay* gave an illustration of forceps of his own designing in which the pin was omitted, he having accidentally discovered that the lock was equally firm without it. The first illustration of the Chamberlen forceps appeared in Giffard's work before mentioned, which was published in 1734. Chapman states that the forceps were well known in 1733. The original form was straight, and the modification by the introduction of the pelvic curve appears to have been invented independently and at about the same time by Levret in France and in this country by Smellie and Benjamin Pugh. The latter who practised as a surgeon in Essex, was the author

of a *Treatise on Midwifery* (1754), in which are contained illustrations of the long and short curved forceps. Smellie became acquainted with the forceps (Duse's) through Butler's *Edinburgh Medical Essays* (1735), and finding them inefficient set about to improve them. He contrived his short forceps, which proved the most efficient instrument of the time. By the invention of the lock which did away with the necessity of a movable axis for the blade, and by the later adoption of the pelvic curve, he produced an instrument which has not been essentially modified or improved by succeeding obstetricians. Although Smellie took so prominent a part in the development of the forceps he was restrained in the use of them, for he states that “only 10 out of 1,000 labours required instrumental delivery.”

### Fillet and Lever

The fillet was used occasionally by the eighteenth century obstetricians and ingenious contrivances were invented for passing the traction-cord over the child's head. Chapman must have had some liking for the instrument, since he kept his method of using it secret when he published the account of the forceps. But after Smellie had pointed out that it was liable to tear the scalp of the child and Pugh had expressed the opinion that “all kinds of fillets were but idle things” it was generally abandoned by skilled practitioners.

Not so the lever. This instrument underwent many modifications from the original model of Roonhuyzen, one of the best designs being that of Lowder, a well known lecturer on midwifery in St. Saviour's Churchyard, Southwark, and graduate of the University of Aberdeen (1775). Several manuscript copies of Lowder's lectures are in existence and show him to have been a judicious and interesting teacher and an experienced practical obstetrician. He gives an excellent account of the pelvis and its measurements and discusses the possibility of detecting pelvic deformity by general inspection, stating that deformity may be suspected if the patient has had rickets or has a great falling in of the back and projection of the nates,

“but,” he adds, “here we must be certain that the appearance of the falling in of the back and projection of the nates is not owing to the fashion the ladies have nowadays of wearing cork rumps.” Some claimed that Lowder's lever was equal or superior to the forceps, but it is clear that they must have used the instrument to alter the position of the child's head rather than to extract it. An ingenious modification was Aitken's “living lever,” in which the curve of the blade could be increased after it had been introduced so as to form a sharply curved surface by which to make traction on the occiput and thus convert a “face” into a “vertex” presentation.

### The Treatment of Contracted Pelvis

The conservative principles which underlay the practice of Hunter, Smellie, Hunter and Denman led to difficulties when applied to severe degrees of pelvic contraction. Minor degrees allowed version or the use of the lever or forceps and it is surprising to read how seldom any other method was required. It is to be regretted that we have no exact statistics of the mortality of cases so treated, but the rarity of cases in which one or other of these operations was not possible suggests that cases of severe pelvic contraction were less often met with than at the present day. In order to get over the difficulty in severe cases British obstetricians proposed to diminish the size of the passenger, either by the induction of premature labour (first carried out by Dr. Macaulay) or by reducing the size of the child by restricted diet (first carried out by Lucas of Leeds in 1794).

Symphysiotomy, which was performed for the first time in England by Welchman in 1782, has never gained general favour among British obstetricians. In the eighteenth century it was condemned by the Hunters and Denman and only favoured by Lerke and Aitken, the latter in 1785 proposed his “new pelvotomy,” the precursor of the modern pubiotomy, in which the ramus of the pubis and ischium were to be sawn through on each side “so that the anterior segment of the pelvis becomes movable and yields to the pressure of the child so as to allow delivery.” John Aitken was a surgeon and man midwife who practised in Edinburgh,

and founded, in 1784, a lying-in hospital in which about 100 women were delivered annually.

Cæsarean section in the eighteenth century was almost always fatal to the mother. In Ireland it had once succeeded, and then it was performed by an ignorant midwife, Mary Donally, in 1738-39, in England the first successful operation was performed by Barlow of Bolton in 1793, and in that case the child did not survive. The operation was stigmatized by Ould as a "detestable, barbarous, illegal piece of inhumanity." Although Smellie and Buton in the middle of the century, and Hamilton and Denman at the end, had accepted the operation for cases of extreme pelvic contraction, Osborn denied that either Cæsarean section or symphysectomy was ever a justifiable operation. He described cases of the severest degree of pelvic contraction in which he had been able to deliver by means of craniotomy, and, recognizing that the recovery of the mother depended on its being performed before she became exhausted, he extended the indications to cases which perhaps might have been delivered by forceps, and thereby attracted a good deal of censure, especially from foreign obstetricians, as the enthusiastic advocate of mutilating operations. In favour of Osborn it must be remembered that Cæsarean section and symphysectomy were at that time almost uniformly fatal, that British obstetricians have always regarded the child's life as less valuable than the mother's, and that fatal results to the mother from craniotomy depend almost entirely on its being performed too late. William Osborn, a friend and fellow lecturer of Denman, was born in London in 1735. In 1770 he joined Denman in founding a school of midwifery, and became one of the most successful teachers, more than twelve hundred practitioners of midwifery having attended his lectures.

For the performance of craniotomy either a guarded knife or scissors was employed, of which Smellie's scissors-perforator was the most practical. In the extraction of the child's head after perforation the crochet was mostly used—at first the straight instrument, afterwards the curved crochet, and finally (by Smellie) the double crochet. Opinions differed as to whether the instrument should be fixed inside or outside the skull. The forceps were also used for extracting the head (Smellie), or the forceps with a crochet at the end of the blade (Pugh).

#### *Hæmorrhages and Convulsions*

The hæmorrhages most frequently recorded at this period were of the ante-partum variety, due to separation of the placenta either normally situated or prævia. Gifford was the first British author to point out the occurrence of true placenta prævia, as distinguished from prolapse of the organ. The treatment was sometimes rupture of the membranes, but usually podalic version. Post-partum hæmorrhage was treated mostly by sedatives and tonics, but sometimes by local styptics, the disadvantages of which were recognized. Cold applications were also employed. There is no record of the employment of manual compression of the uterus. Several cases of hæmorrhage due to inversion of the uterus are described, in some of which recovery followed the reduction of the inversion. A few cases of rupture of the uterus are mentioned, one of these is illustrated by Denman in a fine plate.

Convulsions were treated by bleeding, blistering, opiates (extract or tinct thebæic), hot baths, and clysters. The temporal artery or jugular vein was often recommended as the vessel to be opened.

#### *Ectopic Gestation and Hydatidiform Mole*

Interesting cases of these conditions were published by Gifford, with illustrations. The ovum of the ectopic gestation was passed by the rectum, to which the sac adhered. The case of hydatidiform mole terminated fatally a year after the delivery, a tumour being found in the uterus, which was thought to be the placenta, but was probably a chorion-epithelioma.

#### *Summary Review of the Period*

It may be said that during the one hundred and fifty years after Harvey published his *De Generatione Animalium* a great advance was made in the science and

art of midwifery. This was chiefly due to the introduction of male practitioners, many of whom were men of learning and devoted to anatomy, the groundwork of knowledge. The institution of lying-in hospitals by these male practitioners had an important influence in promoting teaching and research. The general introduction of the use of forceps placed in their hands means, previously unknown, of delivering women, and by its results gradually came the opposition of the midwives, surgeons, and physicians to the new class of men-midwives. The establishment of the College of Physicians in instituting a diploma of "Licentiate in Midwifery," was not without influence in improving the status of those practising midwifery, although it ceased to be granted in the nineteenth century.

The characteristic of British midwifery at this period was conservatism. Although by some practitioners carried to excess, it led to laudable attempts, exclusively directed to avoid the operations of craniotomy which endangered child, and of Cæsarean section and symphysectomy which so often proved fatal to the mother.

The forceps were sometimes used unnecessarily then, now, but the abuse of operative methods of delivery is much greater at the present time, and no better corrective of that abuse could be prescribed than a study of the careful records of the British obstetricians of the seveneenth and eighteenth centuries, showing the resources of that "perfect operative" Nature in effecting delivery.

## CHEMICAL CHANGES ACCOMPANYING MUSCULAR ACTIVITY

BY

THOMAS HUGH MILROY, M.D., F.R.S.E.,  
Dunville Professor of Physiology, Queen's University, Belfast

As the subject open for discussion deals with the chemical changes associated with muscular activity it is necessary in the first place to consider the nature of the constituent which probably play a part in the energy changes associated with activity. These chemical changes are mainly concerned with the transformations of glycogen. As the transformations are brought about by the action of enzymes within the muscle, those must at all times be present. The evidence of enzymatic changes having been in progress, and thus it is to be expected that the products of ferment action should be present in varying amounts, the variations depending upon the conditions under which the muscle has been placed. Thus when muscle is removed from the body and the conditions are such that the removal of the products of ferment action cannot be effected either by oxidation, owing to the predominantly anaerobic conditions existing, or by diffusion away from the muscle, then we should expect to obtain evidence of the accumulation of the products of degradation of the glycogen. The extent of the breakdown process will be determined by the activity of the ferments under the physical conditions existing, by the inhibiting effect on the enzymes of the products of their activity, and, in the case of acid production, by the reaction alterations in the medium. It is therefore evident that in intact, and in moribund in minced muscle tissue, living or dying, and under anaerobic conditions, the enzymatic products of the anaerobic degradation of glycogen should increase. The relative amounts of the glycogen and the products of enzymatic action on this carbohydrate in muscle tissue has been quickly removed from the body, and in the case of ferment action is checked by such a process as fermentation will give some information as regards the equilibrium established normally between the mother and the products of its enzymatic disintegration.

On examination of such muscle tissue it is found that there are present, in addition to glycogen, a number of products which have been derived from it—namely, in the case of polysaccharides, hexoses, phosphoric acid, and lactic acid, and hexoses, and lactic acid, not to speak of products of fermentation.

A paper in the *Proceedings of the Royal Society of Edinburgh* 1927.

precursors of the lactic acid. The work of Fletcher and Hopkins may be regarded as the starting point of the modern investigations. These investigators emphasized, in the first place, the rapidity of the formation of lactic acid in muscle under anaerobic conditions, especially in minced muscle tissue, and in the second place, the extent to which this process might be checked by rapid freezing. Their work also directed attention to the aerobic removal of lactic acid and the significance which they attached to the so-called lactic acid maximum attracted the attention of other investigators, and has undoubtedly been of great value in the search for the immediate precursors of lactic acid. It is not necessary in this brief statement to refer at all fully to this work, nor to the investigations which rapidly followed, as they have been so well summarized in special articles and monographs by Embden,<sup>2</sup> Meyerhof,<sup>3</sup> and A. V. Hill.<sup>4</sup>

The study of the rapidly changing phases of activity in stimulated muscle is an extremely difficult one. From the thermodynamic standpoint the investigations of Hill and Meyerhof have given extremely valuable information. They have shown that the initial phase in a contraction is essentially an anaerobic one, and therefore it is during this stage that the products of ferment action on the glycogen may be expected to appear, and up to the period of aerobic recovery, to accumulate. The periods dealt with in a single muscle contraction are so short that it is naturally impossible by chemical analytical methods to follow the process in the way that has been so successful in connection with heat production. Although much ingenuity has been shown in the endeavour to trace these changes, there is still some difference of opinion as regards these initial anaerobic chemical changes during the contraction of muscle. The initial anaerobic heat production according to Hill and Meyerhof is associated with the formation of lactic acid from glycogen, and the neutralization of the former by the bases readily obtainable from the alkaline salts of such weak acids as the proteins and phosphoric acid. There is still some uncertainty as to whether the lactic acid production is the sole source of the initial anaerobic heat production.

Recent Embden and his fellow workers<sup>5</sup> have dealt with this question, and have expressed the view that in muscle contraction the early exothermic changes in the anaerobic phase possibly have their origin in changes in the physical state of the intrafibrillar colloids. Whether such changes play a part in the initial anaerobic phase or not it is necessary to gain as much information as possible regarding the cycle of changes through which the enzymatic degradation of glycogen takes place. It is for this reason that it appears to me advisable to refer more fully to recent work on the enzymatic processes in muscle carried out by Meyerhof and his school,<sup>6</sup> as these investigations are gradually elucidating the problem which is so difficult of solution—namely the role of the phosphates in the intermediate carbohydrate metabolism in muscle. To Embden and the Frankfurt school we are indebted for the knowledge that we possess regarding one (or more) of the phosphoric acid esters met with in muscle—the so-called lactacidogen. They have studied carefully the conditions under which this body is formed and undergoes disintegration, and have contributed valuable information regarding its general nature. For the first time the close association between alcoholic fermentation by yeast and the carbohydrate transformations in muscle was shown, and now we find that at each step in the further investigation of the role of the phosphates in the two processes, striking similarities in behaviour are becoming manifest.

It appears evident that an extremely important role is played by labile phosphoric acid esters in both mechanisms, but it is extremely difficult to determine from chemical analyses the exact nature of such bodies. The time has certainly not yet arrived for dogmatic statements in connection with the relationship between the free phosphate and its labile and stable ester forms. Evidence however, is accumulating that the chemical constitution of the stable form is different from that of the unstable one and that the former may be regarded as the store of hexose phosphate which has passed out of one active stage in the production of lactic acid. The formation and disintegration

of this stored more stable hexose phosphate may, however, be influenced by alterations in the condition of the living muscle tissue. The recent suggestion of Meyerhof and Lohmann (quoted by Neuberg and Lebowitz)<sup>7</sup> regarding the probable mechanism in the case of yeast fermentation is of interest, and a process of the same type may possibly occur in muscle. The suggestion is to the effect that in the first stage of the esterification process two molecules of hexose may react with two molecules of phosphoric acid to form two molecules of the monophosphoric acid ester, and that in the second stage one of the molecules of this ester may take up another molecule of phosphoric acid to form the diphosphoric acid ester leaving one molecule of reactive sugar free. If such a process does occur, the diphosphoric acid ester may be regarded as the stable form, having passed out from the active cycle and become a storage product. The part played by such esterification processes in rapid changes of activity in muscle has still to be made clear but from the study of the enzymatic transformations of the precursors of the esters, when the process is carried out slowly with the extracts of muscle prepared by the Meyerhof method, much valuable information has already been obtained. These extracts have been obtained from amphibian and also from mammalian skeletal muscle, and they can be tested under conditions when the main action is an amylolytic one, or one of esterification with or without lactic acid formation. I have also carried out a number of experiments with similar extracts from mammalian muscle, and in general my results confirm those obtained by Meyerhof, Lohmann, and other associated workers.

Some of the most striking results obtained from these investigations will now be referred to. The first change effected in the carbohydrate cycle is the amylolytic one, carried out by a ferment with a temperature range of activity greater than that of the others. Thus this action in mammalian muscle can take place at temperatures not only suitable for subsequent esterification (20° to 37°) but at higher temperatures (40° to 45°), and also at acid reactions which would inhibit the later process of esterification and glycolysis. If the process be studied at 25° to 37° under conditions where there is a free supply of glycogen, and only the small amount of free phosphate extracted from the muscle by the cold saline solution then following the amylolytic process, there is an esterification one which is accompanied by lactic acid formation. If such an extract contained, for example, per cubic centimetre, slightly over 0.5 mg.  $H_2PO_4$ , in the form of free phosphate along with, say, 6 mg. glycogen, esterification would proceed slowly with an approximate equimolecular production of lactic acid and removal of free phosphate. This formation of lactic acid can proceed until practically all the free phosphate has disappeared. It is evident that in such a case a process is going on by means of which an ester in a stable form is being produced along with the lactic acid. Such a process might be accounted for by the production of a monophosphoric acid ester in the first place (the unstable form), followed by the taking up of an additional molecule of  $H_2PO_4$ , so that in the process at each stage two molecules of the monophosphoric acid ester would be transformed into one of the diphosphoric acid ester, leaving a molecule of reactive sugar for lactic acid formation.

The stable hexose diphosphate so formed may, however, like the original ester in the muscle, be itself the source of lactic acid production, just as pure alkaline hexose diphosphate in solution may be broken down by muscle extracts to form in equimolecular proportions lactic acid and phosphoric acid. This process is essentially different from the first one as regards the necessary activating agents. For the first process the co-enzyme is required and for the second it is not. The phosphoric acid set free in the disintegration of the hexose diphosphate may, however, be used up, on the addition of glycogen or starch, and thus the muscle extract may initiate again the combined processes of esterification and lactic acid.

What, then is the effect of a fluoride addition to a mixture capable of carrying out such esterification and glycolysis? In those circumstances, just as in muscle tissue, esterification alone proceeds, not only without lactic acid

production, but very frequently, with an actual disappearance of part of the acid originally present. The esterification process in this case has resulted in the formation of phosphate esters of a stable form.

A most interesting accompaniment of this purely esterification process, without lactic acid production, is an increase in acidity, and the swing in reaction is of the same order as in the case of the less complete esterification with accompanying lactic acid production which use the natural changes in the saline mixtures without fluoride. This rise in acidity in fluoride mixtures in which esterification is proceeding is undoubted. According to Meyerhof and Suranyi both the mono- and the di-phosphoric acid esters are stronger acids than orthophosphoric acid. Meyerhof and Suranyi compare this rise in acidity accompanying the linkage of phosphoric acid with the sugar with the well known increase in acidity which boric acid shows on condensation with mannitol. There can be no doubt that such a change does occur during the enzymatic process, and the acid swing on esterification, even in such artificially well buffered solutions as 0.025-0.030 molar phosphate, is a constant feature of fluoride esterification without any lactic acid production. The reverse effect of diminished acidity, produced by a simple hydrolysis of the stable ester without or with very little lactic acid formation, has also been noted by Meyerhof.

Before leaving this subject reference requires to be made to the action of such extracts on glucose, fructose, or other hexoses. Only under special conditions—and the same is true for muscle tissue itself—can the hexoses undergo esterification and glycolysis. The natural muscle extract, therefore, contains the necessary activators for the complete glycolysis of glycogen or starch, and not of the hexoses, or at least of those only to a slight extent.

Meyerhof has obtained distinct lactic acid production of the fermentable hexoses with fresh extract of rabbit's muscle. I have been unable to detect anything beyond a very slight acid production, and that not sufficient to change the reaction of a 0.025 molar phosphate solution. When, however, an activator obtained from yeast is added, these hexoses break down with great rapidity. In the process half is esterified and half broken down to lactic acid. The lactic acid production in the first phase is proportional to the amount of free phosphate present, and on the addition of more phosphate esterification increases.

It is therefore to be borne in mind that the normal carbohydrate present in muscle is the one from which the carbohydrate-phosphate transformations most readily start, and that, in the process of degradation of glycogen, esterification associated with a rise in acidity occurs, and also that labile esters are intimately concerned with lactic acid production. From what has already been said it is evident that the intermediate stages in glycolysis are concerned with labile ester forms which it may be impossible to identify in the chemical examination of resting or active muscle tissue.

In the study of the chemical changes accompanying activity of muscle investigators have naturally directed attention mainly to the glycogen, lactic acid, and the lacticidogen. Enrichment upon the glycogen store and equivalent production of lactic acid in anaerobic transformations has been established, and the fate of the lactic acid in oxidative recovery has been very thoroughly investigated by Meyerhof and Hill. The transformations of the intermediate body, lacticidogen, have been more difficult to elucidate. Being an intermediate body, the amount present at any time is conditioned by the balance struck between its formation and its breakdown. In any definite type of muscle, therefore, it is present at a fairly constant value, and even in activity the rate of its breakdown may only slightly exceed that of its formation.

Embsen and his fellow workers have, in a series of investigations dealing with direct and indirect stimulation of isolated muscle preparations, studied the increments in free phosphate and lactic acid derived from the precursor lacticidogen. It is necessary to bear in mind that, as regards the phosphoric acid increments, these are set free by the breakdown of what is possibly the stable ester form. The preliminary investigations of the Liggletous\* point to a possible unstable phosphate compound which they term

phosphagen and which is apparently gradually broken down on stimulation, in rigor, etc. The inorganic phosphate values given by those who use the Embden technique and any other method which involves a possible acid hydrolysis, according to these writers, include the phosphate bound in this labile form. Lohmann and Jendrossky, as well as Embden, have considered the possible hydrolysis of the hexose phosphates under those conditions, and this at least be said—the more stable ester does not break down. The small number of analyses published giving the effect of action on the free phosphates and phosphagen indicate that the low original free phosphate values obtained by the investigators remain unaltered, and phosphagen disappears—that is to say, a labile phosphoric compound has passed into a stable form. That the stable form is produced by the Embden technique, and that additional phosphate and glycogen may be esterified to the stable form under fluoridation is undoubted. Certainly much more work requires to be done on the labile compounds before our knowledge of the initial changes in activity can be regarded as satisfactory.

According to the recent work of Landen the lactic acid rise in activity is not limited to the initial anaerobic period of activity. The accumulation of lactic acid which occurs in the separated muscle on stimulation is to a large extent prevented under conditions where the blood supply is not interfered with. As many of the earlier researchers dealing with this subject are somewhat unsatisfactory, I have recently carried out a series of experiments dealing with the chemical changes in muscle, with blood supply intact, after stimulation and during the period of recovery. In all cases (in the cat) the muscle stimulated on one side could be compared with the same muscle on the resting side, or the stimulated one with the stimulated and subsequently recovered muscle on the other side. The stimulation was just sufficiently strong to bring out contractions, and the rate of the faradic stimulation was one or two per second. The periods of stimulation varied from fifteen minutes to two hours, with recovery periods of eight minutes' to two hours' duration. The results may very briefly be summarized. In all cases the water content of the stimulated muscle was higher than that of the resting one, and within eight minutes of the cessation of stimulation it showed a distinct decrease.

In practically every case, even after fifteen minutes' stimulation, the lactic acid content had risen and the glycogen fallen. In nearly every case the lactidogen values after stimulation were below the normal. When the stimulated muscle was minced and subjected to the action of fluoride, the amount of stable hexose phosphate formed was smaller than in the case of the unstimulated muscle treated in the same way. This was most evident when excess of the precursors of the ester, glycogen, and phosphates was added to the mixture. Within an eight minute period for recovery the muscle, which was practically free from glycogen when examined immediately after the stimulation, had commenced to replenish the exhausted store. The percentage of water fell during the recovery from 79.8 to 78.5 per cent, the lactic acid rose, and lacticidogen removed, but there was no early evidence of fresh buildup of lacticidogen. After a longer period of recovery (twenty minutes) the storage of glycogen, the removal of excess lactic acid and water, and the return of the lactidogen to its original value were all evident. The recovery of the esterification process under fluoride followed the restoration of glycogen by the muscle.

It appears, therefore, that during the period of stimulation there is an entrance of water which occurs rapidly, and this is accompanied by the changes which are characteristic of incomplete aerobic recovery. There can be no doubt that, after a period of activity which has resulted in practically complete removal of glycogen, the muscle is able to contract almost as well as at the outset. The energy cycle of changes is evidently now starting with the products of the enzymatic disintegration of the glycogen.

It appears probable that changes in permeability in active muscle fibres are characteristic accompaniment of activity, and that even after moderate stimulation there is a disturbance in the water exchange resulting in a rise in fluid. The free phosphate (determined by the method) when calculated for water-free muscle (Embsen's

ring the period of stimulation and a fall during that of recovery. Throughout the periods of activity and recovery there must be a free interchange of anions between the muscle fibres and their environment, but the phosphate ion is free by disintegration of the hexose phosphate does not rapidly leave the muscle. During the period of recovery the excess free phosphate is used for esterification.

It is to be hoped that soon the nature of many of the chemical changes associated with activity which are still unknown may be cleared up—for example, the transformations in the sugars prior and subsequent to esterification, the nature of the immediate precursors of the lactic acid, and the mode of the endothermic conversion of lactic acid to glycogen.

# DISCUSSION

Professor Otto MEYERHOF (Berlin) considered that the significance of the chemical processes accompanying muscular activity, which were first laid bare by the pioneer work of Fletcher and Hopkins on lactic acid lay chiefly in their supplying energy for the mechanical work. Summarizing a recent investigation in his laboratory, he said that energy was measured by heat of reaction, and therefore the problem arose of correlating the heat during and after contraction with the chemical processes occurring simultaneously. A V Hill had discovered that the heat was divided into two distinct phases of about the same magnitude, the first phase (so-called initial heat) coinciding with activity and independent of oxygen, and the second phase (so-called delayed heat or heat of restitution) continuing for several minutes after the mechanical response but only in the presence of oxygen. Professor Meyerhof had demonstrated some years ago that the first anaerobic phase was dependent on the formation of lactic acid from glycogen the second phase on an oxidative process in which only a quarter of the lactic acid or a corresponding amount of carbohydrate was burnt, while three-quarters were re-oxidized to glycogen. During the anaerobic phase there were liberated on the average 390 calories per 1 gram of lactic acid which number was named the caloric quotient of lactic acid. When this acid was removed in the restitution phase with combustion of 1/4 gram of glycogen hydrate, one expected

$$\frac{3780}{4} = 945$$

representing the heat of combustion of glycogen hydrate per gram and 390 calories the reversal of the heat liberated in the first phase. These 555 calories were 1.4 times the 390 calories of anaerobic heat. Thus anaerobic heat stood to oxidative heat in the proportion of 1 to 1.4 this proportion was similar to the findings of Hill and Hartree in their myothermic experiments. The speaker then considered the question as to how the 390 calories of anaerobic heat were to be explained. The difference of the combustion heats of dissolved glycogen and diluted lactic acid—the initial and final products of the reaction—amounted only to 160 to 185 calories according to the speaker's own measurements. Exactly the same value was found during the formation of lactic acid in cut muscle suspended in phosphate solution and also in recent experiments in which the glycogen was fermented by the muscle enzyme in aqueous solution. Undoubtedly the mere transformation of glycogen into lactic acid only accounted for about 160 calories. But in the intact muscle the lactic acid reacted with muscle protein according to the abbreviated equation

by de-ionizing the protein. If the whole or the lactic acid reacted in this way 140 calories would be liberated corresponding to the heat of de-ionization of proteins. But as was found in collaboration with Dr Lohmann, only half of

the lactic acid formed during fatigue was neutralized by alkali proteins, the remainder by phosphate and other buffers. Therefore only about 70 + 10 = 80 calories were to be expected from neutralization. Altogether 260 to 270 calories were covered by known reactions, and for the origin of about 120 calories the explanation was lacking. Attempts for many years to find a higher heat of de-ionization in the living muscle or a measurable amount of energy by colloidal changes had been in vain.

P and G P Eggleston in the Instituto of Professor A V Hill and Fiske at the Harvard Medical School, had simultaneously found that two-thirds to three-quarters of the whole phosphate in muscle which was believed to be inorganic was in reality in a very labile combination, which, as Fiske had demonstrated, contained besides phosphate also creatine in equivalent amount. This labile compound, named by the Egglestons "Phosphagen," was decomposed in large part during the anaerobic fatigue during the oxidative restitution it was rebuilt similarly to the carbohydrate. In experiments which were made in collaboration with Dr Lohmann concerning the breakdown of phosphagen by muscle enzyme, Professor Meyerhof had found that sugar and lactic acid were never formed in this way. Preparations of phosphagen, about 90 per cent pure, showed a molecular weight, dissociation curves before and after splitting, and kinetics of hydrolysis which agreed with the simple formula of 1 molecule of phosphate and 1 molecule of creatine obviously bound together by the amino group of the creatine thus it was a phosphamide with the structure  $R-NH-PO(OH)_2$ .

In confirmation of the suggested constitution was the fact that all the known simple phosphamides behaved similarly, they were stable in alkaline and unstable in weakly acid solutions. The splitting of phosphagen into phosphate and creatine gave a heat formation of 150 to 160 calories per 1 gram of phosphoric acid on the other hand it was found, in confirmation of the work of the Egglestons that during muscle activity the ratio of phosphagen breakdown to lactic acid formation was not constant but decreased with fatigue. However, in an anaerobic fatigue of average degree leading to an accumulation of 2 mg of lactic acid in 1 gram of muscle, 80 to 90 per cent of the available phosphagen was split. This meant a production of 1.5 mg of inorganic phosphoric acid, or 0.75 mg of phosphagen phosphoric acid per milligram of lactic acid, which gave 120 calories. This was exactly the value which was so far unaccounted for as a portion of the "caloric quotient." Thus the heat of contraction was caused not only by the anaerobic splitting of carbohydrate and associated physico-chemical reactions, but also by a second metabolic process, till now completely unsuspected—namely the formation of creatine from a precursor. It followed, on the other hand, that the caloric quotient could not be exactly the same during the whole course of fatigue, but must sink from a higher to a lower value corresponding to the diminishing amount of phosphagen split. The ratio between phosphagen split and lactic acid formed was about twice as high in the beginning of fatigue as in the calculation used above. The decrease of the caloric quotient in higher degrees of fatigue was found in the speaker's earlier experiments an increase on very short stimulation was indicated, but could not be proved because of the insufficient accuracy of the measurements. He stated that it is purposed to reinvestigate this shortly. All voluntary muscles formed lactic acid from glycogen during mechanical work, while the occurrence of phosphagen was limited. Eggleston had not found it in the muscles of invertebrates in which E Mellanby had shown that creatine was lacking. The speaker had found that the muscle of the crab (*Astacus*) contained no phosphagen, but another phosphate compound which behaved similarly in chemical and physiological respects and was apparently a substitute for phosphagen. Probably therefore phosphagen like bodies played a universal part in the activity of striated muscle. It was most remarkable that while the main part of phosphagen was restored only in oxidative recovery a small part of the amount split during the tetanus was immediately afterwards rebuilt apparently in the moment of relaxation. The energy for this might be afforded by lactic acid formation, or the restabilization might be immediately due to

the mechanical and elastic change corresponding to Hill's heat of relaxation. Although the older hypothesis of a double mechanism in muscle, tonic and contractile, due to creatine and lactic acid respectively, had not been verified in these experiments, some dualistic theory regarding the part played by creatine and lactic acid formation in contraction apparently had now become necessary. There were doubtless several other metabolic changes during activity of muscle, such as the formation of ammonia studied by Tashiro, Embden, and Parnas. Professor Parnas in Lwow (Poland) had found that during injury, rigor and also during mechanical work ammonia was formed, in quantities of about 1 molecule  $\text{NH}_3$  to 14 molecules of lactic acid, in proportion to the amount of work done. But the amount of ammonia was quite independent of the presence or absence of oxygen, and remained unchanged during recovery. This  $\text{NH}_3$  was given up to the blood stream in the intact animal and was apparently the cause of the increased nitrogen metabolism during work, found by Rubner, Cathart, and others. While this reaction is well as others completed the intimate picture of the metabolism of working muscle, he believed that the chemical happenings decisive for the supply of energy were now quantitatively known. In addition to the breakdown of glycogen and its resynthesis in recovery, the splitting of phosphagen and its rebuilding from creatine and phosphite furnished an important part of the energy supply of muscle, both together were responsible for the heat of contraction.

Professor G. EMBDEN (Frankfurt-on-Main) directed attention to the problem of ammonia production in muscular contraction. The question arose during work on lactic acidogen, the muscular substance which formed lactic and phosphoric acid. The extraction of this substance from fresh muscle was very difficult because it was associated with a nitrogen-containing body, finally, however, the two substances were completely separated. The lacticidogen could be isolated as a crystalline bromine salt and as an amorphous barium salt, of a hexosemonophosphoric acid of a special kind. The nitrogen-containing substance was definitely identified with an already known body—namely, adenosinphosphoric acid, which had not till now been found as a mononucleotide in nature. Adenosinphosphoric acid seemed to occur in a rather large amount in fresh muscle, though during its isolation the greater part was lost. The fact that adenosinphosphoric acid could be got especially out of quite fresh muscles, while inosinic acid was obtained from the extraction of muscles not quite so fresh, led to the conclusion that there was a very close biological connection between the two substances, which, as the formula showed, only differed in this respect—that in the purine nucleus in place of the inosinic acid had an hydroxyl group and the adenosinphosphoric acid an amino group. The adenosinphosphoric acid could easily pass into inosinic acid by simple hydrolytic de-amination, and this led to the idea that the formation of ammonia in dying muscles, previously observed and recently confirmed by Grd Andersen, might have its origin in this de-amination. Grd Andersen had thought that this *post-mortem* ammonia formation might have its origin in *in-vivo*, while Meyerhof, who had found ammonia formation in isolated diaphragm muscle, believed that it came from proteins. Rebeleg, Selters, and Embden had shown that the spontaneous formation of ammonia in dying muscle was greatly increased by the addition of the sodium salt of adenosinphosphoric acid. Gerhild Schmidt had been able to transform adenosinphosphoric acid into inosinic acid by the effect of a ferment solution procured from muscle. These processes, which were originally found in dying muscle, were later recognized as characteristic accompaniments of activity. The lactic acid formation in dying muscle had long been known, when Fletcher and Hopkins investigated the formation of this acid during activity. Also the production of inorganic phosphoric acid was at first recognized as a dying phenomenon and only later as a characteristic accompaniment of every muscular contraction. The close relationship between chemical processes in active and in dying muscle had led the speaker to investigate whether there was ammonia formation in active as well as in dying muscle. Experiments by Richings, Embden, and War-

meier had shown that severe fatigue of isolated muscles was associated with a very great increase in ammonia content. Quite independently Parnas and Morolowski had described ammonia formation in the case of isolated frog muscles, and it could also be demonstrated during muscular activity in the living frog. The gastrocnemius of frogs which did not jump and whose ammonia content was about 2.2 mg. for 100 gr. muscle. In frogs killed forty-five minutes later, it increased to 5.1 mg., and seventy-five minutes later, ammonia reached 9 mg. The resting of previous isolated muscles was followed by the disappearance of ammonia both in isolated muscles and in living animals, the ammonia content in one case was 13.8 mg. before, and after 1 hour's rest 9.6 mg. These frogs had been examined in May, in the other summer months ammonia increased so strongly, owing to the frogs being less active. Thus in June the ammonia content was 2.6 mg. before and 2.1 mg. after rest. Great variations were only seen in the month of May, at which time the frogs were much more lively than at any other time. At every time, however, the quantity of ammonia was greater in the frogs than in quiet ones, and in the esculenta species than in the *temporaria*. In general, less was found during the night than in the day, and a well marked concentration in living frogs might be regarded as a sign of fatigue.

When the gastrocnemius of both sides were tetanized a short time in the same circuit, and the muscles of one side then immersed in liquid air at the height of tetanus, while the muscles of the other side were fixed after a resting period of ten to sixty seconds the ammonia content of the muscles which were immersed later was found to be much lower than the others. This result was obtained in five winter experiments performed in frogs which were in good condition. Recent experiments by Miss Kristensen and Miss Schumacher indicated that the ammonia split off by a quite short tetanus was not rebuilt or at least not completely rebuilt during relaxation. In these experiments the first muscle was not immersed at the height of the tetanus, but immediately after relaxation the second one minute later. In all experiments in which the muscles relaxed immediately after the cessation of the stimulation less ammonia was found in the muscles later immersed. It seemed as if the muscles of frogs kept for a long time in the laboratory were less able to re-synthesize the ammonia split off during tetanus, and the same was true for frogs caught only a few days before the experiment during summer heat. Such muscles behaved after one short tetanus like fatigued muscles. Therefore it seemed necessary to perform experiments concerning the reversibility of the ammonia formation during muscular contraction on frogs on such frogs which had been caught immediately before the experiment.

From the experiments mentioned it was evident that during muscular contraction not only lactic acid and phosphoric acid were formed, but also ammonia appeared. Twenty years previously Slosser, working on dogs, had found in augmentation of ammonia during muscular activity, and recently Tashiro had shown that during stimulation by single induction shocks isolated frog muscles gave off more ammonia than resting ones. The latter experiment could be explained apparently, as well as the augmentation of ammonia in the moment of contraction by a diminution of muscular acidity at the moment of contraction. Some years previously it was found that the lactic acid and inorganic phosphoric acid were ruled by the same mechanism, and in both cases it was found that adenosinphosphoric acid brought about much more rapidly than inorganic phosphoric acid the disappearance of inorganic phosphoric acid. The experiments were performed on the preparation of rabbit muscle. It seemed probable that the effect of adenosinphosphoric acid might be of the greatest importance for the rebuilding of lactic acid after muscular work. In the experiments on frog muscle phosphoric acid was determined in the phosphagen content. The differences, therefore, in the phosphagen content as is known from the work of the French school, could not be split in strong acid reaction, could not be detected. The experiments should accordingly be repeated with attention to the phosphagen change. Nothing of the

about the energy change effected by the ammonia reaction in muscular contraction. The hydrolytic deamination of adenosinophosphoric acid in the formation of the acid, on endothermic reaction, could be toned up by secondary processes following the de-amination regarding the importance of ammonia formation in the genetic changes, experimental investigation was required to determine whether all the ammonia formed in muscular contraction came from adenosinophosphoric acid, or whether there were other sources of ammonia. Unpublished experiments by Wassermann emphasized that there was no other ammonia-forming substance than adenosinophosphoric acid (perhaps adenosin). In every future attempt to explain the entire process of muscular contraction from a chemical viewpoint attention would have to be paid to the ammonia reaction during contraction.

Dr F. GOWLAND HOPKINS (Cambridge) remarked that there was a time-honoured assertion that the biochemist did not have to deal with the actual events in living tissue, but since from the very moment his methods were applied to them the tissues ceased to be alive. This assertion had been shown to be baseless by the advances already made in the chemistry of muscular activity. Progress had been real that they had, perhaps, become unduly light-hearted in contemplating the problems, recent discoveries had shown that there were complexities hitherto unsuspected. Some important points sharp differences of opinion were developing, but since those who disagreed were experimentalists and not theorists, ultimate agreement would eventually be reached. The speaker referred to the study in his laboratory of muscles which, after a prolonged stay in oxygen at low temperatures, had become completely insensitive, their irritability being again restored by immersion in solutions of certain electrolytes. The facts observed seemed likely to throw light upon the conditions which determined a normal response to a stimulus.

Professor T. H. MILLAR, in reply, referred briefly to the nature of the linkage of the phosphoric acid in the compound described by Professor Embden, and commented on the importance of the recent investigations which had just been reported. Within a comparatively short period our knowledge of the chemical changes in muscular activity had been greatly extended.

### MISCELLANEOUS PAPERS

FOLLOWING the discussion on the chemical changes accompanying muscular activity a number of short papers dealing with physiological and biochemical subjects were read. Brief abstracts of some of these are printed below.

#### THE CONSTITUTION OF THYROXINE

Dr C. R. HARRINGTON (London) detailed briefly the steps which led up to the isolation of thyroxine in the pure condition. It appeared that the first indication that the physiological action of the thyroid gland was concerned in any way with iodine was obtained by Koerber (1895), who made the observation that the administration of iodine had a favourable therapeutic effect in cases in which the thyroid function was deficient. In the same year the significance of this observation was extended by the work of Baumann, who demonstrated the actual presence of iodine in the thyroid gland, and was further able to indicate a rough parallelism between the iodine content of various preparations of the gland and their physiological activity. This discovery made it at once apparent that any attempt to isolate the active principle of the gland involved a systematic pursuit of the iodine. Baumann himself started experiments in this direction, and found that simple extraction of the gland with water and alcohol removed relatively little of the iodine, which, therefore, was apparently bound up more or less firmly with the proteins. On the other hand hydrolysis of the gland with dilute sulphuric acid yielded a product (iodothyron) which contained variable but larger amounts of iodine (5 to 14 per cent) than the original gland and also showed an enhanced physiological activity. In the light of present knowledge this substance was to be regarded as impure thyroxine.

A similar substance was obtained by Hutchinsan (1898) by peptic digestion of the gland, and by Oswald (1902) by acid hydrolysis of an iodine-containing globulin which he extracted from the gland with dilute saline. By no method, however, could iodothyron be prepared with a constant chemical composition. No further progress was made with the problem until, in 1919, Kendall announced the isolation of a pure crystalline substance from the thyroid which contained 65 per cent of iodine, and which exhibited in a high degree the typical physiological action of the gland. On the basis of elementary analysis Kendall ascribed to this compound the empirical formula  $C_{15}H_{13}O_4NI_4$ , he further propounded a constitutional formula

regarding it as a derivative of oxindolepropionic acid (hence the name "thyroxine"), and as being ultimately derived from tryptophan. This formula, however, presenting as it did inherent chemical improbabilities, was advanced without any experimental support.

The continued absence of any evidence as to the true chemical nature of thyroxine led Dr Harrington, in 1925, to take up the problem of its constitution. For this investigation the primary requirement was the possession of a fairly large amount of the pure substance, and a method had therefore to be devised which would give a better yield than the very small one obtained by Kendall. The method of the latter worker consisted in hydrolysis of the gland with 5 per cent sodium hydroxide followed by a complicated process of salting out of the thyroxine, first as the barium salt and then as the sodium salt, the ultimate yield being 0.001 per cent of the original gland. It was found that a considerable improvement was effected by substituting barium hydroxide as the hydrolytic agent and by conducting the hydrolysis in two steps, a preliminary mild hydrolysis of the whole gland being followed by an intensive hydrolysis of the partially purified product. In this way about twenty-five times Kendall's yield of pure thyroxine was obtained, and it became possible to accumulate a sufficient quantity of material for the investigation of its chemical structure.

The first step in this investigation was the removal of the iodine, this was accomplished by means of hydrogen and palladium, a method which could easily be shown to induce no secondary changes in the molecule, and which therefore yielded a product which was certainly identical with thyroxine, save for the substitution of the iodine of the latter by hydrogen. This iodine-free product (desiodothyroxine) proved to have the empirical formula  $C_{15}H_{13}O_4N$ , which, in turn, indicated that the formula of thyroxine must be  $C_{15}H_{13}O_4NI_4$ . Desiodothyroxine further turned out to be an  $\alpha$ -amino-acid with one phenolic group and two benzene rings in the molecule, a systematic process of degradation indicated, indeed, that the formula was

that is to say, that the compound was the *p*-hydroxyphenyl ether of tyrosine. The correctness of this hypothesis was proved without great difficulty by the synthesis of this compound and the identification of the synthetic product with that obtained from thyroxine. Thyroxine was therefore proved to be a tetra-iodo derivative of the above compound.

The synthesis of desiodothyroxine did not, however, assist in the synthesis of thyroxine itself, since the four iodine atoms could not be introduced directly, nor could direct evidence be obtained as to the positions occupied by these atoms. The fact that two iodine atoms were apparently taken up directly with ease, together with various other considerations, led to the hypothesis that in thyroxine, the iodine atoms were present in pairs, one in each of the benzene rings A and B. Since it was evidently the inner ring B which was resistant to direct iodination,

the actual pinprick. Professor McDowall suggested that the emotions which caused this vaso-constriction might be looked upon as conditioned sensory stimulations. In physiology it had long been known that actual sensory stimulation caused a rise of blood pressure. It was very interesting that the rise of blood pressure which could occur under conditions of mental stress might be considerable. For months he had his blood pressure taken daily, and quite accidentally it was found that on one occasion before an important lecture his blood pressure rose from a normal of 110 to 160, and remained up for several hours. Previously Leonard Hill and more recently Gillespie had shown similar rises of blood pressure in response to mental effort. He had little doubt that this rise of blood pressure was designed for the facilitation of muscular activity, which in a civilized life did not necessarily accompany or succeed mental stress.

Their next step had been to determine how far these two causes might influence ordinary individuals at work. The investigation was just in its infancy, but even already some very suggestive points had cropped up. His colleague Wells had found that in some individuals there was a diurnal variation, which they believed to be associated with mental stress. There was often in women a pre-menstrual fall and a post-menstrual rise and what was extremely interesting from the toxicologic point of view, a definite influenzal fall and a post-influenzal rise. The same individuals when fatigued did not show the diurnal variation.

These observations were being extended to other forms of toxæmia with a view to determining if the response to other toxins was the same and if so, to what extent different individuals responded similarly.

#### NATURAL ARREST OF HAEMORRHAGE

Professor JOHN TAIT (Montreal), in a communication dealing with the natural arrest of hæmorrhage from a wound, said that throughout the animal series there were arrangements whereby any accidental wound of the blood-containing system became plugged by the intervention of the blood. The common belief was that the plasma was particularly and exclusively involved in closing any accidental orifice. In all the invertebrates possessed of blood or body fluid it was the corpuscles that played a part; they adhered to the edge of the wound in the vessel and by successive accumulation became aggregated into a resistant gummy mass which acted as a plug. A similar phenomenon also occurred in the case of vertebrates, the corpuscles involved being the special elements called spindle cells or thrombocytes. The question then arose whether coagulation of the blood plasma assisted in arrest of hæmorrhage. Where the bleeding occurred into the meshes of areolar or connective tissue coagulation was induced. If the vessel previous to puncture had been carefully denuded of its adventitial sheath the only method of arrest was by agglutination of thrombocytes—platelets in the case of the mammal. The speaker illustrated his remarks with lantern slides.

#### THE CIRCULATION RATE

Dr H. WHITRIDGE DAVIES (Leeds) and Professor B. A. McSWINEY (Leeds) contributed a joint communication and described experiments in which estimations of the circulation rate in dogs were made by the Henderson-Haggard ethyl iodide method. The results showed very considerable disagreement with those determined simultaneously by another and more reliable procedure. It was found that the most important fundamental assumptions of the ethyl iodide method were erroneous: thus the coefficient of distribution of ethyl iodide between alveolar air and arterial blood was found to be approximately 52 instead of 20 as stated by Henderson and Haggard. Moreover considerable quantities of ethyl iodide were found in the mixed venous blood. Under certain conditions the difference between arterial and mixed venous concentrations of ethyl iodide was approximately equal to the alveolar concentration multiplied by two. This fact would account for the reasonable results obtained in many instances, the two errors tending to cancel one another. Such a cancelling was however purely fortuitous and could not be relied upon. In some cases, where pulmonary embolism occurred, the relation between the concentration of ethyl iodide in the arterial

blood and in the mixed alveolar air was markedly disturbed. Similar disturbances would occur in any pathological condition in which the normal relationship between alveolar ventilation and pulmonary circulation was upset. The automatic method of sampling alveolar air described by Henderson and Haggard, when applied to dogs gave results which were remarkably consistent and reasonable. The alveolar carbon dioxide pressures agreed closely with those of the arterial blood obtained indirectly by determinations of its carbon dioxide contents and dissociation curves.

## OPTIC NEURITIS

### I—ETIOLOGY DIAGNOSIS PROGNOSIS

BY

J. V. PATEYSON, M.B. F.R.C.S.E.D.,  
Ophthalmic Surgeon, Royal Infirmary, Edinburgh

By the term "optic neuritis" the oculist usually means a certain type of morbid changes which he sees at the optic disc on examination of the fundus of the eye. He recognizes, however, that parts of the nerve other than its distal end, though not visible with the ophthalmoscope, are also liable to be affected by changes such as oedema or inflammation, and in speaking of the cases he usually employs the term "retrobulbar neuritis."

The optic disc has been perhaps the most carefully studied of all the parts of the fundus oculi, and naturally very complete descriptions of the morbid appearances have been given, and even the relation of these appearances to local pathological and anatomical findings have been fairly well made out, though opportunities for the anatomical and pathological examination of early cases of optic neuritis are of very rare occurrence.

During the long time that has elapsed since the early descriptions of morbid appearances at the disc a great deal of confusion seems to have gradually developed, owing to a vague, uncertain, and variable nomenclature. New names intended to define or describe certain types of disc change have been introduced and terms such as "optic neuritis," "papilloedema," "choked disc," "papillitis," and "neuro-retinitis" are now freely used. The sense in which the oculist uses these terms will depend a great deal on the view he has formed, or has been taught, regarding the etiology or the pathological significance of the changes he has under observation. In my opinion the classification of cases of optic neuritis should be based on a full investigation of the cases as a whole, and not merely on the observer's idea of the type of disc changes present. When the cases are studied from this wider point of view it will be readily admitted that those associated with increased intracranial pressure may be at once placed in a class by themselves. This differentiation depends not only on the type of the disc changes—for example, the amount of swelling—but also on the examination of the vision (the absence of any pronounced visual disturbance in the early stages being of paramount importance in the diagnosis). Many of the older case records where optic neuritis or double optic neuritis is noted as occurring, but without proper record of the presence or absence of visual symptoms, leave the reader guessing as to the significance to be attached to the term "optic neuritis."

With regard to the study of the changes at the disc I can well believe that the use of the Gullstrand ophthalmoscope is of the very greatest importance, and I hope that the younger school of ophthalmologists in this country will have more opportunity of using this valuable instrument than their predecessors have had. While freely admitting that many cases of disc change can be instantly and correctly interpreted as due to intracranial pressure, there are many cases where, especially in the early stages, the diagnosis cannot be made with any certainty from the disc appearances. Vision at least in the early stages is in the vast majority of the cases little if at all affected.

\* The opening paper of a discussion on optic neuritis in the Section of Ophthalmology at the Annual Meeting of the British Medical Association at Edinburgh. The President, Dr A. H. H. Sinclair, was in the chair.

Any noteworthy defect of central vision must be fully investigated in order that its cause and significance may be rightly understood. Careful study of the visual fields may in certain cases be of the greatest importance in helping to locate the position and extent of an intracranial disturbing factor. The results of lumbar puncture, as determining the presence or absence of increased pressure, or in revealing the presence of cellular elements or microorganisms in the spinal fluid, are often of great value. The part played by the x-ray plate is familiar to us all, though some may agree with me that the interpretation of x-ray photographs of the skull requires much careful study and experience. In my opinion the reading of the x-ray specialist is often of less value than that of the clinician who has studied the case in its various aspects, and is also equipped with a wide personal experience of x-ray photography of the skull. The Wassermann reaction is now so uniformly taken in cases of this kind that it hardly requires mention. The co-operation of a neurologist in seeking to establish a full diagnosis is taken for granted. Having, then, made up our mind by careful study of a case that the disc changes are a manifestation of increased intracranial pressure, what descriptive group name shall we give it? "Papilloedema" is simple and expressive, but hardly tells us enough—merely, indeed, that the disc is swollen. Some expression such as "pressure-oedema" seems to be needed, and Dr. Triguera has boldly coined the term "pleiocephalic oedema" to define the type of change met with in this group.

With regard to the etiology of the disc changes in this group, there is now a general consensus of opinion that the intracranial pressure is the all-important deciding factor, and further, that the changes observed, at any rate in the early stage, are due primarily to an oedema of the tissues involved. In what way the increased pressure acts—whether, for example, by pressure on the retinal vessels inside the nerve sheath, or by obstruction of the flow of fluid along the lymph paths in the nerve—does not seem to be yet fully determined. Experiments on animals to bring about increased intracranial pressure seem to have been most successful in producing disc changes when direct fluid pressure was used. Apparently it is very difficult indeed to produce by artificial means a slowly increasing intracranial pressure such as is caused in man by a growing cerebral tumour. The theory that the papilloedema (or choked disc) was caused by the action of irritating or toxic fluids circulating within the nerve sheath seems now to have fallen into disrepute, and is negatived by many clinical observations, and by the fact that the relief of pressure is so effective in bringing about disappearance of the swelling of the disc. This was specially shown by the great pioneer work of Victor Horsley, who proved once for all that after timely relief of pressure by operation, the swollen disc will more or less quickly sink to its former level, and the stage of atrophy with ultimate loss of vision be prevented.

In recent years Cushing and Walker in America, by great advances in methods of examination and a highly elaborated and brilliant surgical technique, have demonstrated to the world that intracranial procedures of extraordinary magnitude and complexity can be carried out with comparative safety. While recognizing the limitations and very serious risks of these procedures, I would nevertheless support the view that cases of increased intracranial pressure with changes at the disc should be operated upon in the early stage, so that the patients may have the best chance of retaining vision. Those cases in which more than a palliative trephine is indicated should, in my opinion, be operated upon only by a surgeon who has had very special training and experience in this class of work. Brain abscess may be said to form a special group of cases treated on special lines. Once the stage of optic atrophy is reached experience has shown that the results of operative treatment are apt to be very disappointing. In some cases, indeed, operation seems to have hastened the onset of blindness. Only in definitely syphilitic cases does medical treatment seem to have any real chance of effecting a cure. From occasional cures of this kind sprung, no doubt, the old maxim "Try iodide," a method of treatment which used to lead to much unwarrantable delay. As you are all

aware, prolonged increased intracranial pressure is caused mainly by intracranial neoplasms, but also by cysts, abscesses, gummatous or tuberculous nodules, intracranial aneurysm, and blood extravasations, and in some cases by sinus thrombosis, meningitis, skull deformities, etc.

I should like here to allude to those cases of optic neuritis following severe penetrating head injuries. The vast amount of evidence obtained during the war has shown that disc changes are of very frequent occurrence in these cases—say in 30 to 50 per cent. Only some of these cases appear to be due to increased intracranial pressure. In very many of them there is the added complication of sepsis, often with the retention of foreign matter within the cranium. In many of these cases the general symptoms are so severe that anything like detailed investigation of visual symptoms is quite impossible, and no really accurate clinical differentiation of the type of disc changes can be made. Having no personal experience of this type of case, I should like specially to hear something of the experience of those among us who saw very large numbers of these cases during the great war.

I will now pass on to consider the cases of optic neuritis not depending upon increased intracranial pressure. These are due, in the main, to inflammatory processes in the nerve or its sheath which may lead directly or indirectly to disc changes. In a very large proportion of the cases, however, these inflammatory processes are situated too far from the eye to produce any visible signs at the disc during the acute stage, though later a certain amount of atrophic change almost always becomes visible. In cases with changes at the disc the amount of swelling is usually much less than is so often typically shown in the former group. It may be worth while to give a very condensed rendering of Behr's description of this type from von Hippel's article in the *Gräfe Saemisch Handbuch*, though, as I have already stated, it is impossible to establish a diagnosis by ophthalmoscopic examination without consideration of the whole clinical picture.

"This type does not present the transparent glassy swelling of the papilla so characteristic of the oedema accompanying increased intracranial pressure. The disc rapidly becomes less transparent and the lamina invisible. The roots of the vessels become veiled by swollen nerve fibre tissue. This veiling of the vessels extends some way from the disc. The colour of the disc is usually redder, the veins are apt to be greatly distended, and the arteries small."

While a description of this kind may hold good in many cases, still, as I have already said, it is often impossible to make any certain differentiation of type by ophthalmoscopic appearances. Disturbance of function comes into prominence in this group. Central scotomata with visual failure is common and characteristic, though not invariably present. This failure of vision seldom depends upon any changes which may be visible at the disc, but on the presence of inflammatory foci in the course of the nerve, and the defects in the field of vision will depend on the position and severity of the lesion interfering with nerve conduction. The course of these cases is variable, and in some the general condition of the patient gives evidence of severe general disease, as, for instance, in syphilis or meningitis. These cases do not form a clinical group so well differentiated as the previous group due to increased intracranial pressure. For clinical and descriptive purposes I have tried to subdivide them, following in the main von Hippel's classification.

(1) A somewhat small group characterized by inflammatory processes which develop within the nerve sheath and spread by contiguity to involve the nerve. In the early stage vision may not be much affected, and in a large proportion of cases it is the peripheral, rather than the central, part of the field that first shows visual disturbance. In this group syphilis is a very important causative factor. This probably accounts for certain cases of optic atrophy in young children with a positive Wassermann reaction. A case of the kind with severe infiltration of the meninges, nerve and optic disc is figured in von Hippel's article. I have not seen a large number of cases of syphilitic meningitis affecting the optic nerve and with changes at the disc, but I think all I have seen showed changes in the vitreous in the shape of opacities. I have examined many cases of optic neuritis in patients with meningitis, mostly from ear trouble, and

in my experience the disc changes did not usually appear till a very late stage of the disease and may have been due to increased intracranial pressure. Tuberculosis appears to be a very rare cause of optic neuritis except in cases of intra-cranial nodules causing pressure oedema of the disc.

(2) I now pass to the great group of cases of optic neuritis due to toxins circulating in the blood and giving rise to an inflammatory focus in the optic nerve. Very occasionally infective organisms may actually settle in the nerve but the great natural tendency to recovery in this group of cases negates the idea of actual microbial infection of the nerve being anything but an extreme rarity. In some few cases the inflammatory process affects the nerve head directly but usually it is extra-ocular or retrobulbar. If close to the eyeball signs of inflammatory action are likely to appear at the disc. The swelling in this case is however an inflammatory reaction due to the toxins in the neighbourhood. Our specialty shows in a variety of ways how easily this may take place—for example, in swelling of the orbital tissues before there is actual invasion from an inflamed sinus, or great oedema of the conjunctiva from a str.

The symptoms, course, and prognosis very seldom appear to be modified by the presence or absence of changes visible at the disc. In the majority of the cases disc changes are absent in the early stages, and the diagnosis of optic neuritis has to be made from a careful study of the visual disturbance and of the history and general symptoms. As a rule one eye only is affected. Changes at the disc if present, usually amount merely to a varying degree of redness and swelling with a blurring of the margins, but in some cases the swelling may be very gross, and accompanied by retinal haemorrhages. The diagnosis is made not from the disc changes but, as I have just stated, from consideration of the visual disturbance and of the case as a whole. The visual disturbance is usually very obvious owing to the presence of a central scotoma of a fairly large size. According to Trinquar the centro-caecal type of scotoma is common while arcuate defects from the blind spot arching over the macular region are also of frequent occurrence. The scotoma is usually intense but may vary in different parts. In some cases the scotoma breaks through to the periphery by a narrow neck.

Recovery of peripheral vision usually precedes the disappearance of the central defect. Even when normal vision by the test type has been restored a careful examination will often show slight depression of the central area especially for small coloured objects. In many cases recovery is only partial and in nearly all cases more or less pallor of the disc appears as a permanent record of the attack. Probably many slight cases where vision is less disturbed never seek medical advice recovery rapidly taking place. Chronic cases are very rare unless we admit tobacco amblyopia into this group (I do not propose, however to deal with these forms of toxic amblyopia due to alkaloids and other poisons).

Care should be taken in the diagnosis of retrobulbar neuritis and in cases with a small central scotoma a very careful examination of the macula must always be carried out. In hysteria we have to deal rather with a peripheral than a central field defect. It has also to be remembered that the lesion may be situated far up the nerve and, by involving the chiasm, cause a defect in both fields. Among well established causes of retrobulbar neuritis disseminated sclerosis holds the first place. I remember well reading the original account of the after history of cases of retrobulbar and unilateral optic neuritis examined in the Tübingen Clinic. Since that time among my private cases I have had several patients in whom disseminated sclerosis in its fully developed form followed a retrobulbar neuritis after the lapse of many years. The importance of this connexion between the eye condition and this wide spread nervous affection is everywhere recognized.

There remain, however a large number of acute cases for the origin of which an adequate explanation is wanted. Some perhaps many of my audience will at once say to themselves "This explanation has been found it is of course merely an invasion of the nerve from the posterior nasal sinus." After the researches of Onodi and others

on the anatomical relations of the optic nerve to the posterior ethmoid and sphenoidal sinuses this explanation appears most convincing and plausible, but to me the proof is altogether wanting. I admit at once that many cases of retrobulbar neuritis, mostly of a chronic persistent type, have arisen from involvement of the nerve in the inflammatory affection of a sinus, and I also admit that these cases have undoubtedly been cured or relieved by free operation on the diseased sinus. What I do not yet believe is that the common acute retrobulbar neuritis which ophthalmologists so often meet with has been proved to be due to a spread of inflammation or of inflammatory products from the sinus into the nerve, in such a way as to create an inflammatory focus which would explain the symptoms.

I have worked in this department of the Infirmary for more than thirty years, and during a large part of that time this department has been in closest touch with a highly organized, up-to-date, and very energetic ear and throat department situated at our doors. During that time our department has been in the habit of sending to the ear and throat department a large number of cases of acute sinus trouble the patients having come to us on account of pains in the neighbourhood of the eye suggestive of trouble especially in the frontal or ethmoid region. In the great majority of the cases our diagnosis was confirmed by our rhinological colleagues and proper treatment employed. None of these patients came to us on account of visual disturbance which is of course, the outstanding symptom of retrobulbar neuritis. Very rarely have I seen a case even of severe sinus trouble sent to us from the ear and throat department on account of a visual defect, although our colleagues were well aware of this possibility. So far as I know the ear and throat department has never sent us a case of acute sinusitis with complaint of visual trouble.

Some years ago the Scottish Ophthalmological Club had a meeting with the rhinologists belonging to a similar club to thrash out this vexed question, which was at that time so prominent in the medical press, especially in America. A committee was formed of oculists and rhinologists to co-operate in the investigation of these cases. The oculists were to examine the cases of sinus trouble for visual disturbance, and the rhinologists were to examine the noses of cases of optic neuritis for nasal disease in any form. The inquiry began with some enthusiasm, but faded away to nothing because little if anything was ever found, the oculists finding the eyes of the sinus patients healthy, and the rhinologists finding the noses of the retrobulbar cases healthy after careful investigation, but without opening the sinuses.

Now I was educated for a long time in the Vienna school, and am an ardent admirer of the critical sagacity of that school. I therefore read the recent publication of Professors Møller and Hirsch with great care but, I am afraid, I still remain abjectly unconvinced. Møller as von Kries takes up a rather extreme position. He admits that retrobulbar neuritis occurs very rarely in severe sinus disease, and ascribes the type commonly seen to acute sinus trouble of a kind which apparently gives no signs in the nose to ordinary examination. Hirsch's account of changes found in the mucosa on opening the sinuses is to me unconvincing. Møller lays great stress on the success of operative treatment, the successful methods of treatment being of the most varied kinds and ranging from the boldest surgical interventions to scratching of the turbinates or the mere application of cocaine or adrenaline.

Unfortunately, I have had no time to look over the old records of acute retrobulbar neuritis, but I know that it has always been regarded as a disease where the prognosis was almost certainly favourable. Curiously enough I have had experience of several private cases where operation was deferred, and where recovery took place before the nose was interfered with. Think how the rhinologists and the patient would have been alike impressed by the almost miraculous restoration of vision within a very short time after the operative treatment on the nose. I do not know any kind of cases in the whole range of medicine where one is more likely to be deceived with regard to the efficacy of operative measures than these cases of acute retrobulbar

neuritis in young adults. After all, how many patients do we meet with in hospital or in private practice with one eye blind from an atrophy probably due to this cause? With regard to the pathological findings in the mucous membrane of the sinuses opened by operative intervention, one is struck by their insignificance, and would like to hear further reports on these findings. However, I still remain open to conviction, and if there is time I should like to hear opinions on this really important question, for, after all, there must be some source of infection.

After this great group of cases which we class as retrobulbar there remain yet to be considered some small subsidiary groups, such as the neuritis following inflammation in the anterior segment of the eyeball, neuritis attending gross vascular disease, and the so-called neuro-retinitis, which is, of course, usually a sign of general systemic poisoning, as in Bright's disease and diabetes. None of these three groups seem to be suitable for discussion at the present time, and, as I have already stated, I have said nothing on such conditions as tobacco amblyopia.

I should like, however, to call attention to cases of severe affection of the nerve in myelitis, and to those rare cases of very severe acute optic neuritis with sudden blindness or extreme loss of vision. I will leave any discussion of these cases to Dr. Ronne and others with special knowledge of the subject.

## II—NOMENCLATURE OF THE CONDITION

BY

HENNING RONNE, M.D.,  
Copenhagen

The ophthalmologist must consider the diagnosis, inflammation of the optic nerve, not only on account of the danger which this disease by itself entails for the visual nerve of the patient, but he must also regard such inflammation as a symptom of serious affections of the brain of various kinds, symptoms which are of the greatest importance for the neurological diagnosis.

In order to be able to apply the information which the examination of the eye may give, it is naturally necessary that the neurologist should understand what meaning the ophthalmologist attaches to the terms by which he characterizes the various conditions. It is an unfortunate fact that the terms "choked disc" and "neuritis optica" have several meanings, and it is still more unfortunate that the two parties, ophthalmologists and neurologists, make use of the terms in these several meanings, so that misunderstandings are apt to arise.

The terms "choked disc" and "neuritis optica" are mostly used as ophthalmological morphological expressions, of which the former is employed for the swollen neuritic disc, the limit of swelling being conventionally fixed at an elevation of not less than two diopters. In this way the terms are clearly defined, and in practical respects this distinction is of importance because the swollen disc is far more frequently a sign of intracranial hypertension than the disc which is not swollen. But in itself it is not the degree of the swelling which interests the neurologist—he will ask the ophthalmologist about something quite different. Is the neuritic change of the disc an oedema which indicates disease of the brain—in particular an increased intracranial pressure—or is it an indication of a local inflammation of the trunk of the optic nerve?

But here there is clearly no question of ophthalmoscopic appearances, but of clinical, pathological, anatomical ideas which demand from the ophthalmologist a combination diagnosis with all its possibilities of error. It is true that this diagnosis is in most instances very easy, but sometimes the conditions may be rather more difficult.

It is not always a simple matter to decide whether in a given instance there exists a primary papillary oedema with functional disturbance resulting from secondary atrophy of the nerve fibres, or whether there is a primary lesion of the optic nerve with secondary papillary oedema. Here I will only mention the not very rare cases of choked disc with sudden initial blindness. Later on I will refer more fully to these cases, but will only point out here

that opinions do not agree as to indications for treatment in such cases, because the question as to the primary cause of the disease is not quite solved.

With typical fresh choked disc in a case of brain tumour reduced central vision as a consequence of macular involvement may erroneously cause the assumption of a primary focus in the optic nerve. In English it must be very well be reasonable to use the term "choked disc" for the ophthalmoscopic morphological idea, and, on the other hand, the term "papillary oedema" for the pathological-anatomical idea, but even a well considered and consistent use of these terms would not quite solve the difficulty.

The fact that papillary and optic nerve affections in cases of neuro-retinitis albuminurica are pathologically and anatomically very closely related to choked disc, possibly also in their pathogenesis, will probably not give rise to much difficulty, since such an important pathogenic symptom as hydrophos of the optic nerve sheath is common to both. From a clinical point of view the resemblance is striking, as the papillary oedema in albuminuric retinitis is almost always small. The pathological-anatomical identity in this case will hardly give rise to difficulties in diagnosis or in terminology.

The situation is less fortunate in regard to intraocular interstitial neuritis optica, which forms the opposite to the choked disc clinically, but not in pathological-anatomical respects. It is true there exists, particularly in Germany, a generally adopted opinion that papillary affections, as in the case of interstitial inflammations of the optic nerve, are of genuine inflammatory character, the same as the affections of the trunk of the optic nerve. This is expressed by the attempt to introduce special terms for genuine papillary inflammation—"papillitis," "entzündungspapille" (Behr)—and as a result Behr's attempt to attain ophthalmoscopically a reliable differential diagnosis between papillary oedema and papillary inflammation.

In my opinion, however, this method is not possible. The examination of a large number of optic nerves with a variety of affections, performed partly by myself, partly at my request by Hugo Thomsen, has shown me that even if there exists an actual inflammatory condition of the optic nerve, the papillary affection is, in the clear sense of the word, always an oedema. In one patient with a very severe syphilitic gummatous inflammation of the optic nerve, it appeared that the inflammatory infiltration almost reached the lamina cribrosa. Even in this case the papillary affection was almost purely an oedema, as there were only very slight cellular changes anterior to the lamina cribrosa. The general statement made here that the ordinary intraocular neuritis optica is an oedema of the condition of the papilla, immaterially whether the ophthalmoscopic change is due to an interstitial neuritis, to a tuberculous meningitis with secondary interstitial neuritis optica, to a gummatous infiltration of the optic nerve, or to a purulent meningitis, is supported by independent pathological-anatomical examinations, and is also in accord with F. Klauber's examination of neuritis optica in cases of bullet injuries in the skull. In my opinion there is reason to suppose that the idiopathic inflammation of the optic nerve, with which we are familiar in consulting practice and in which there is rarely an opportunity for pathological examination, behaves in a corresponding manner. It is not denied that, in the case of severe inflammatory processes in the optic nerve situated very far forwards, round cell infiltration may be observed to extend to within the eyeball. There is, however, a method which enables us to detect whether the inflammation of the optic nerve extends to the papilla itself to a recognizable degree. This sign is the appearance of opacities in the vitreous body. It is, in any case, difficult to imagine inflammation of the papilla with a clear vitreous body. A familiar with clouding of the vitreous in papillary affections, not only in the rarer cases of tuberculous gummatous papillary swelling, which may appear in the form of pronounced choked disc with opacities in the vitreous, but also in the more frequent neuroretinitis of the optic nerve after salvarsan treatment, in which the opacities of the vitreous are not uncommon (Sjögren). By personal experience I can confirm this, and I think it should be regarded as a real papillary inflammation.

If the opinion which has been expressed here is correct, it is obviously hopeless to attempt an ophthalmoscopic differential diagnosis between inflammation and oedema of the optic nerve. As in by no means few cases affections of this nerve arise from a combination of increased pressure in the brain and infiltration of the nerve, this cannot be done for other reasons also. We must surely, as in the past, be satisfied with restricting ourselves to the knowledge that the high grades of papillary oedema are most frequently caused by increased brain pressure. Normally the intraocular neuritis optica is the opposite to the so-called retrobulbar neuritis. Although nominally these two ideas are absolutely contrary the one to the other, they are not so much so in reality. This is because intraocular neuritis optica is an ophthalmoscopic term, while retrobulbar neuritis has in the course of time, become a term for a clinico-nosological group of diseases which is characterized by other features than the negative fact that no ophthalmological changes can be observed in the papilla.

There is, therefore, nothing against a retrobulbar neuritis occasionally showing the ophthalmoscopic picture of an intraocular neuritis and even so strongly that it can be called a choked disc but this is of course, the exception. In the group of retrobulbar neuritis I also include chronic toxic amblyopia, Leber's hereditary neuritis optica, the usual acute typical retrobulbar neuritis, and lastly the violent diseases of the optic nerve which not seldom introduce or accompany acute disseminated myelitis—that is to say, diseases which vary from the sudden development of bilateral total blindness to the almost occult affections of the optic nerve the only symptoms of which are atrophic decoloration of the temporal part of the papilla with normal vision, the picture we frequently find with commencing disseminated sclerosis.

Notwithstanding the undoubtedly different clinical characters which present themselves, and the entirely varying etiological factors which we can prove as the cause of these conditions we nevertheless find such common peculiarities that it is justifiable to classify them as a special group of diseases of the visual field related to each other. Of the clinically common features of these diseases which belong to the retrobulbar neuritis group the most constant is the negative central scotoma, and in particular its appearance where the ophthalmoscopic changes are slight or absent. The more acute forms are characterized by violent onset, accompanied by pains in the temples, pain on movement of the eyeball, and sensitiveness to pressure upon it. To these is added a more or less definite tendency to spontaneous recovery, which, indeed, is less distinct, though not quite absent in the more protracted forms. The exact connexion between these more chronic processes and the acute cases is proved by the circumstance that both may have the same etiology. Disseminated sclerosis can thus show itself both in acute disease of the optic nerve and in quite slowly developed atrophy of a type very much resembling intoxication amblyopia. Parallel to the tendency to spontaneous recovery is also the feature common to the whole group of diseases—namely, that the prognosis is rarely quite hopeless even though it may vary much in accordance with the etiology and the clinical type and, lastly the ophthalmoscopic final result the temporal papillary atrophy which is common to all the etiological members the group comprises.

On the other hand, this group of diseases is not characterized by any single one only of the symptoms mentioned. Otherwise typical cases of retrobulbar neuritis can show choked disc the orbital pains are often missing in the slow cases the tendency to spontaneous recovery may be but little apparent as in Leber's hereditary neuritis, but even here it still occurs in a certain small percentage of cases. The disease may also temporarily spread beyond the macular bundle and even cause total blindness, and the central scotoma may be absent while the other symptoms are typical (Ronne).

Whether a disease should be included as a form of retrobulbar neuritis must, therefore be decided according to its entire clinical picture and not in respect of a single instance or a single symptom.

Although the pathological anatomy of all these diseases is not in all respects particularly well known, it seems

that here also conditions may be found which are common to the whole group. As far as the acute forms are concerned it is beyond all doubt that the anatomical basis is an irregular and but little bounded plaque formation in the optic nerve. This is known both from disseminated sclerosis, myelitis, idiopathic retrobulbar neuritis, and retrobulbar neuritis in cases of ethmoiditis, in the more chronic forms also it appears that the same conditions occur. In a microphotograph of the optic nerve of a patient with diabetic intoxication amblyopia it could be seen that the degeneration of the macular bundle had a distinct and strong maximum in the most posterior part of the orbital portion of the nerve, quite as a plaque. In another case there was a focus of acute degeneration with lipid and fatty granular cells in the macular bundle in each optic tract quite distinctly outlined, while the bundle in front and behind was hardly pathologically degenerated. Corresponding conditions are also met with in cases of alcohol amblyopia, though more developed owing to the degeneration of the entire macular bundle in its whole length.

A point which is of special interest is the relation between axis cylinder and medullary sheath. As you know, it is a special peculiarity of disseminated sclerosis, and also of its optic nerve lesions, that the medullary sheath is destroyed before the axis cylinder, and this is considered to be one of the characteristic features of the disease. The question might be raised as to whether the bare axis cylinder in the optic nerve is a peculiarity common to the whole group of diseases here under discussion. As a matter of fact there is evidence in support of this view. In diabetic intoxication amblyopia this has certainly been observed by Frazer and Bonze as well as by myself in acute myelitis by myself, and in idiopathic retrobulbar neuritis with ethmoidal carcinoma by Birch Hirschfeld. Plaque formation in the macular bundle has been observed without any secondary degeneration of the medullary sheath, although the cases were sufficiently old to allow the development of such degeneration to have taken place. This can hardly be explained otherwise than by the preservation, partly at all events, of the axis cylinder in the plaque formations.

Even if the examination in this respect may not have been quite as complete as may be desirable there is some reason to suppose that this preservation of the axis cylinder may perhaps also form a common pathologico-anatomical feature of this group of diseases. If this should prove correct we may here possibly find the anatomical condition which determines the relation between all these etiologically quite different diseases. An explanation of the appearance of central scotoma is suggested by the assumption that the macular fibres may be more liable to the loss of their medullary sheath than the peripheral fibres while the almost automatic spontaneous recovery may be regarded as an adaptation of the axis cylinder to the loss of its sheath.

I therefore think that, in accordance with what I have stated, a disease which is characterized by a tendency to attack selectively the macular fibres should be termed "*retrobulbar neuritis*" and only such a disease. But not every disease with normal disc and central scotoma in the field is a retrobulbar neuritis, an accidental localization in the macular bundle of an accidental disease does not, of course, fall under this definition.

After this general review of the three clinical types of papillary oedema neuritis optica, and retrobulbar neuritis, I shall with more regard to the clinical and pathologico-anatomical details, mention a group of diseases of the optic nerve which in a certain way, lie midway between these three clinical types, and which in the same manner are sometimes classified into one and sometimes into another of these types.

I should first like to remind you of the peculiar condition which is called choked disc with sudden initial blindness. Strangely enough it does not seem to have found a collective discussion in the literature, although this would be justified by its practical importance alone, as the question of operative treatment by trephining immediately arises in such a case. Cases have appeared in the literature in which a rapid palliative trephining was performed under

such conditions, and even with excellent results (Nacht, Uhlhoff, Botheig) in so far as, after the operation, sight was regained. It is true that such an apparently good result becomes somewhat more problematic when one sees that recovery or improvement of sight has also often occurred, either spontaneously or after various forms of treatment, in cases in which no operation had been performed.

In order to be able to classify these cases it is first necessary to recognize that the impairment of vision is of a different kind from the impairment which results from secondary atrophy in papillary oedema. This appears from the fact that recovery occurs as a rule, when improvement of vision in ordinary secondary atrophy after papillary oedema would be out of the question, or, at the most, only possible within very narrow limits, even in cases where trephining has removed the increased intraocular tension and with it the cause of the papillary oedema.

The problem can therefore be formulated thus: Is the sudden visual impairment a direct consequence of the choked disc (papillary oedema), or are both parallel and relatively independent effects of the same cause (say an increased intraocular tension), or is the choked disc (papillary oedema) a consequence of the lesion of the visual path which has caused the impairment?

The first possibility, that the papillary oedema may be the direct cause of the loss of sight, appears to me to have very little probability. It is hardly justifiable to compare this motile blindness with the usual observations which occur in choked disc (papillary oedema) because the transitory forms are completely absent.

One might sooner think that the increased intraocular tension causes the weakening of sight in other ways than by the choked disc (papillary oedema)—for example, by pressure on the chiasma by the dilated third ventricle. By such means it is assumed that certain forms of bitemporal hemianopia arise through stretching of the optic nerves, but positive evidence that bilateral total blindness can be caused by such means does not exist.

The third possibility, that the ophthalmoscopically visible papillary oedema is the consequence of a disease in the trunk of the optic nerve, and therefore without analogy with the choked disc of brain tumour, is, in my opinion, the real explanation. Microphotographs of sections of the optic nerve in such a case of choked disc with bilateral initial anisometropia show a sharply outlined plaque (in one only of the sections of the nerve shown) as the most conspicuous feature. Microscopically this plaque is seen to be of a purely degenerative nature, arising from a complete destruction of the medullary sheath, the place of which is filled with a close packing of lipid and fatty granular cells. Another series of sections, through the chiasma from the same case, show that here there are several similar plaques, amongst which is a single large one which extends obliquely through the chiasma from one optic nerve to the opposite tract. This, in combination with the plaques in the nerve, gives a sufficient explanation for the bilateral blindness.

Although the *post-mortem* examination in this case showed that there really existed a brain tumour, it is beyond all doubt that the blindness was not due to choked disc, as the blindness appeared about one month before death, and the otherwise typical and severe choked disc developed only immediately after the appearance of the blindness.

In my opinion it should also be considered as certain that most cases of this kind are not due to a real tumour in the brain, but use recovery from the main disease very often occurs. I shall later on show that I regard these cases as instances of severe acute retrobulbar neuritis. But I should like to draw attention to the apparently paradoxical feature that the appearance of this optic nerve disease is always, or at all events very often, accompanied by diffuse general brain symptoms, such as headaches, vomiting, torpidity, and slow pulse, which would naturally be explained as signs of increased tension in the brain. There exists thus a peculiar and not easily comprehensible connection between the disease of the optic nerve and a

diffuse acute disease of the brain which is often termed pseudo-tumour cerebri.

If it should be thought that under these conditions it would be reasonable to assume a slowly growing brain tumour to be the cause of all cases of this kind this is definitely contradicted by the fact that an affection of the optic nerve of absolutely the same clinical and anatomical character appears in another well known condition, where a tumour in the brain is quite out of the question. I refer to the affection of the optic nerve which so often introduces the appearance of disseminated myelitis. Here we find a not very common, but quite typical, pathological picture which is so closely related to multiple sclerosis that it may justly be called *retinite sclerosiformis*. The resemblance between these two diseases shows itself in many ways (Ronne), but most in the conspicuous fact that the affection of the optic nerve very often precedes the appearance of the spinal symptoms.

In the literature there exists an ample collection of cases of this disease, and on going through these a large number will be found which are initiated by choked disc and sudden blindness (Ludon, Brinno K. Stocking, Rosenfeld, Tschirkowsky, Chisholm, Knapp, Dieschfeld, Ronne), and it is quite characteristic that it is almost the rule that in the commencing stage of this disease the erroneous diagnosis "brain tumour" is made. This diagnosis is frequently amended only after the symptoms of myelitis appear, or at the *post-mortem* examination. The microscopic examination of the optic nerve shows quite unmistakably that the anatomical cause is the same as in the case I have mentioned above—namely, the formation of plaques without the essential phenomena of inflammation, but with an enormous accumulation of lipid and fatty granular cells in the place of the completely destroyed medullary sheath.

In other cases the affection of the optic nerve which precedes the development of the myelitis has a somewhat different character—namely, that of a typical retrobulbar neuritis with orbital pains, characteristic central scotomata, and normal ophthalmoscopic appearance—but still with the same histological picture of irregular plaque formation in the nerve (Abelsdorf), while between these two extremes there exist all possible transitory stages.

On perusing the literature we undoubtedly gain the impression that the affections of the optic nerve are of different kinds as they appear under various names—choked disc, neuritis optica, or retrobulbar neuritis. A closer examination, however, shows that in reality they must represent one single etiological and clinical unit. This may already be deduced from the above-mentioned fact that affections of the optic nerve often precede spinal affections, and, furthermore, from the decided tendency to spontaneous recovery, the progress of which is not interrupted by death, and lastly, from the circumstances, not yet discussed, that the disease is almost constantly localized in the chiasma (Schmid and Gunnar, M. Tschirkowsky, Dolin, Kall, Shrikey and Lawford, Ronne).

It follows, therefore, that the character of the visual fields is determined by this localization, and bitemporal hemianopia has been frequently found (Noyes, Steffen, Elschning, Schanz, Seguin, Ronne). Sometimes a central scotoma has been observed as evidence of a retinal character, but of special interest is the peculiar change in the form of the field defect observed at times—namely, the change from central scotoma to bitemporal hemianopia or vice versa (Noyes, Steffen), or from bitemporal to bilateral defects (Ronne). Later I will discuss more fully this change in the field defect which takes the form of an improvement in the original defect, together with possible improvement in the original defect, together with possible improvement in the original defect. Here I will only state that the cause must undoubtedly be looked for in the plaque formation in the optic nerve, possibly in the healing of previously formed plaques simultaneously with the new formation of others.

The same condition which appears as the serious choked disc, with sudden anisometropia, can also appear in combination with myelitis, or isolated as cerebral pseudo-tumour, while the less violent affections of the optic nerve in myelitis have parallels in independent affection of the

optic nerve at the chiasma without additional special symptoms. Such cases are characterized by plaque formation in the optic nerve and the chiasma and therefore, show partly hemianopic forms of the visual field of varying character. In such cases it is naturally much more easy to study and follow the character and progress of the affection through the form of the defect in the visual field.

These idiopathic cases have, in their general symptoms, in many respects the character of retrobulbar neuritis—sudden commencement often with orbital pains and pain on movement and, in their further course a tendency to recovery. Also, in some cases, the characteristic features of the visual field will closely approach the retrobulbar neuritis type—for example by showing a one-sided temporal hemianopic central scotoma, a type of field defect to which Traquair has given the name "junction scotoma" because it must be due to a lesion at the junction of the optic nerve and the chiasma. In other cases this scotoma will widen to a characteristic three-quadrant scotoma or to bitemporal or homonymous hemianopic central scotomas.

But the condition which is the most interesting is the change in form of the defect in the visual field. This change has often a law bound character the defect naturally shifting across the surface of the visual field. It may wander quite successively and even, as if it corresponded to serpiginous disease which progresses at one point and heals at the point first attacked. Such a type can appear in cases where the affection develops in one optic nerve only, but it can be more easily followed where it appears in the chiasma and the visual fields therefore show hemianopic forms. Here it will be most frequently found that a hemianopic field passes over into a central scotoma, or vice versa, but peculiar changes in the appearance of the field may occur. I will illustrate this by a few cases in which a number of examinations allowed the development of the disease to be followed.

The first case begins with a symmetrical bitemporal downward defect of the visual field. The peripheral defect gradually shrinks and a central scotoma of the usual type forms in the right field whereas in the left a temporal hemianopic central scotoma appears which however, gradually extends somewhat to the nasal half of the field by the formation of a three-quadrant scotoma. Then improvement occurs, resulting in almost complete recovery.

In another case the field defects began as bitemporal hemianopia—in the left field a temporal hemianopia formed in the right a temporal hemianopic central scotoma. In the left eye while the visual field type—temporal hemianopia—remains until recovery (complete recovery), the centre of the field is wholly lost and anisotropia almost develops but later the temporal half of the visual field which was originally most affected is restored, so that the visual field changes from bitemporal to left-sided homonymous hemianopia. Eventually complete recovery ensues. Central vision and the visual fields are restored and only a temporal atrophy of both optic discs finally remains.

A third case shows a nasal hemianopia in the left field which gradually recovers by the formation of an annular scotoma. In the right field a colour defect for red in the lower nasal quadrant, from the periphery to the blind spot persists during the whole progress of the case.

The first visual field in this series was taken four days after the sudden commencement of the disease. The supposed plaque was assumed to lie in the forward left corner of the chiasma.

I have in the course of years seen a by no means small number of cases varying as it true in the ophthalmoscopic picture from choked disc to normal disc and in the affection (defect) of the visual field from double-sided total blindness to limited scotoma lasting from a few days to several months, but always with certain points in common which seem to unite them into a collective pathological picture. In particular, I refer to the storied onset the general or hemianopic central scotoma combined with hemianopic peripheral defects of the visual field in various combinations, and lastly the decided tendency to spontaneous recovery either partial or complete.

The close relation of the pathological picture to retrobulbar neuritis appears to me to be certain. The difference

lie, I think, in the chiasmal location, which is indicated by the findings in the visual field and the pathological anatomical examination. And even if textbooks of ophthalmology have not as yet dealt with independent acute inflammatory conditions of the chiasma, not a few cases have occasionally been mentioned in the literature which correspond to the description I have here tried to give. In recent times I have, in describing the picture of this disease, received the support of renowned authors—in Germany of v. Heppel in Scotland of Traquair.

The diagnosis must of course, be made essentially by the aid of a careful examination of the visual fields, which should be specially directed towards ascertaining whether the margins of the defects, for a shorter or longer distance show a hemianopic limit line in one or both fields. Total and complete hemianopias are only exceptionally found.

I cannot here enter more fully into the technique of such an examination but will only point out that for this purpose the mechanical perimeter cannot be used. Only when the test object is moved freely in the hand, so that the direction of the movement can be chosen by the examiner at right angles to the outline of the defects found can a good result in this direction be expected. For the same reason the campimeter has a decided superiority over the perimeter.

It can be understood that such a pathological picture is also of importance for our therapeutic measures. In my opinion most cases of choked disc with sudden blindness are of this nature and it is evident that if this ophthalmoscopic picture is caused by a focus in the optic nerve, it cannot be regarded as an indication for the performance of a palliative trephining—partly because it does not tell us anything about the height of the intracranial pressure, and partly because the condition itself does not exclude spontaneous improvement even after a long time has elapsed and lastly because there is always a possibility of a myelitis spinalis, which may be caused by so serious a measure as the operation will always be.

The lighter cases, in which the chiasmal hemianopia is the principal symptom, are easily mistaken for the effects of tumours and inflammatory conditions which attack the chiasma from outside and I would specially caution against labelling a patient with the diagnosis "syphilis" because a chiasmal hemianopia has improved under a so-called diagnostic antisyphilitic treatment is repeatedly mentioned, spontaneous improvement frequently occurs.

Nosologically these cases lie at the tangential point between choked disc, neuritis optica, and retrobulbar neuritis. Whether we give them one of these names or, as I think would be most correct, regard them as cases of retrobulbar neuritis localized in the chiasma, is in itself of secondary importance, and will have to be decided by future investigation, particularly in regard to the pathological anatomy of the disease.

### III—OPTIC NEURITIS AS AN AID TO DIAGNOSIS

BY

A. J. BALLANTYNE, M.D.

Consulting Ophthalmic Surgeon, Western Infirmary, Glasgow  
Surgeon, Glasgow Eye Infirmary

My remarks will deal briefly with some aspects of optic neuritis which have presented themselves to me in private ophthalmic practice in the out-patient work of the Glasgow Eye Infirmary and in the wards of the general hospitals.

In the general hospital the ophthalmic surgeon is naturally concerned chiefly with cases selected by the physician or surgeon in which it is expected that the ophthalmic surgeon will be able to give help in diagnosis. Consequently optic neuritis presents itself for the most part under two aspects—namely, (1) as the papilloedema associated with intracranial tumour, meningitis, and other cerebral diseases, and (2) as the optic neuritis or neuroretinitis of renal disease. The immense value of choked disc as an aid to the diagnosis of intracranial new growths as well as its comparative lack of value in the localization of the tumours, is well recognized. At the stage when

these cases usually come under observation the considerable, circumscribed swelling of the disc, the distension and tortuosity of the vessels, and the other characters of choked disc are usually well established, and, taken in conjunction with the other symptoms of the case, leave little doubt as to the diagnosis. No doubt the integrity of central vision in the majority of cases of papilloedema accounts for the fact that the earlier stages in the evolution of the condition are comparatively seldom observed, but it should not be forgotten that choked disc does pass through a stage in which it cannot be distinguished from other varieties of optic neuritis. If the term "papilloedema" is made to include all the optic disc changes in which oedema is a feature, whether they are presumed to be inflammatory or not, it will naturally be applicable to a cerebral tumour optic neuritis from its earliest to its latest stages. "Choked disc" obviously cannot be so applied. Ulthoff, in his Bowman Lecture,<sup>1</sup> defines choked disc as a prominence of the papilla of at least 1.5 to 2 diopters, and he speaks of the necessity of drawing such a precise line, yet he himself includes under "choked disc" a case with little or no swelling, which he believes to show the beginning of choked disc, as well as cases of neuritic atrophy with very slight swelling. The confusion likely to arise from this use of terms is apparent, and points to the desirability of some authoritative definition.

Of definitely unilateral choked disc I have very little experience, but I have recently had under observation a case under the care of Professor Archibald Young in the Glasgow Western Infirmary.

The case was obviously one of cerebral tumour, and the principal ocular signs were pronounced choked disc in the left eye, with merely a slight mistiness of the nasal border of the right optic nerve, a large central scotoma in both fields of vision, with complete loss of the nasal half of the field in the left eye and of the upper temporal quadrant in the right. Other signs were a slight paresis of the right facial nerve and complete nerve deafness on the left side. While unilateral choked disc does not necessarily imply a tumour on the same side of the brain, the field defect in this case pointed to a basal situation, and I endeavored to localize the tumour as involving the lateral aspect of the chiasma in such a way as to interrupt both crossed and uncrossed fibres to the left optic nerve as well as the crossed fibres to the right. At operation this was confirmed and the tumour almost completely removed. The patient, unfortunately, died on the following day, and at the post mortem examination it was found that the tumour, a meningioma, had sprung from the inferior aspect of the left temporo-sphenoidal lobe and part of the adjacent frontal, stretching and compressing the left optic nerve from its outer side also pressing on the pituitary and causing absorption of the bone of the sella turcica. Ulthoff has explained the absence of choked disc in certain basal tumours as due to the occlusion of the communication between the arachnoid space and the optic nerve sheaths by the tumour, but in this case it seems more likely that the choked disc on the affected side was due to direct interference with the venous and lymphatic circulation, and not to elevation of the general intracranial pressure.

The optic neuritis of meningitis differs from that of cerebral tumour in being less prominent and more diffuse, but in tuberculous meningitis, in my experience, the disc swelling is apt to resemble that of intracranial tumour in being of a steeper and more circumscribed character, while in quite a large proportion of the cases diagnosis is simplified by the presence of tubercles in the choroid.

In a special study of 61 cases of cerebro-spinal meningitis during the Glasgow epidemic of 1907<sup>2</sup> I found optic neuritis in 5 cases (8.2 per cent). I have no figures indicating the percentage frequency of optic neuritis in lethargic encephalitis, but I have observed the sign in two cases in private practice. One of these when seen was in a late stage and diagnosis had already been established. The other was a young woman who was seen six weeks after the beginning of an illness which had been characterized by intense headache and sickness with some convulsive attacks. Diplopia was noticed when she began to recover. When examined she had ptosis of the right external rectus muscle, slight ptosis in the left eye, and in intense double optic neuritis with both haemorrhages and exudates on the swollen disc. The fields of vision were full and central vision almost normal. Cerebral tumour was suspected, but further observation in hospital established the diagnosis of lethargic encephalitis, and the patient made an excellent recovery with disappearance of the optic neuritis and diplopia, and restoration of normal vision.

In the surgical wards I have been asked to see a number of cases of head injury, and two of these which came under my notice about eighteen months ago are perhaps worth mentioning in this discussion.

The first was a boy, aged 16, who had a fall from a height of thirty feet. Details of the accident were lacking. When I saw him, six days later, central vision was good and the fields of vision were of full extent, but both discs showed papilloedema (1.5 D of swelling) and there was paresis of the right external rectus muscle. No doubt there was in this case a fracture of the base of the skull, but the papilloedema, in view of the excellent vision and field, could not be due to haemorrhage into the optic nerve sheaths. It would appear rather to have been, as in cases reported by Lister and Holmes,<sup>3</sup> secondary to oedema of the brain produced by concussion.

The other case, which was seen about the same time, concerned a young man of 23, who, on the day of admission to hospital, was riding a motor bicycle and collided with a motor car. He remounted his cycle and went home and was even able to go for a walk, but, in the course of his outing headache developed, and on reaching home he collapsed into unconsciousness. There was no evidence of direct injury to the head. His left pupil was found to be larger than the right and less active to direct light stimulation. When examined in detail, six days after the accident, vision was very much poorer in the left eye than in the right. Double vision was present and tests showed paresis of left external rectus and of the left inferior rectus. The right optic disc was slightly hazy, but the left presented a marked papilloedema with some haemorrhages on its summit and with great distension and tortuosity of the veins. A perimetric tracing showed a homonymous defect situated in the upper right quadrants of both fields. In this case there was ample evidence of fracture of the base of the skull. Leslie Paton in his paper on "Ocular symptoms in subarachnoid haemorrhage"<sup>4</sup> states that "when a condition of amblyopia or amaurosis is present and changes in the discs are seen within a few hours of the development of the cerebral symptoms, and the pupil reaction to light is lost or, if present, is not well maintained, the papilloedema is most probably due to haemorrhage into the nerve sheath." These criteria seem to be satisfied in this case, whence it may be assumed that the unilateral papilloedema was due to haemorrhage into the optic nerve sheath. The homonymous quadrant field defect was an interesting feature and indicated damage to the corresponding segment of the left optic tract. I have had an opportunity of re-examining this patient nearly two years after his accident, and it is interesting to find that although the field defect remains almost unchanged, indicating permanent damage to the optic tract, there has been complete recovery of central vision, and the optic discs are in every respect normal.

A case of a more unusual type, also seen in one of the surgical wards, was that of a man, 36 years of age, who had suffered from gastric ulcer of long duration.

Nine days after a gastro-enterostomy he suffered from haematemesis and melena, and the vomiting was associated with neuralgic pains in the left forehead and eye. About a week later he discovered great loss of vision in his left eye, and my examination showed that the visual acuity of that eye was less than 1/60, that the field of vision was reduced to a small area immediately above the fixation point, and that there was a definite papilloedema in the same eye. He was seen again ten days later, and already the condition of the disc was one of atrophy with blurring of its margins. No vascular changes were visible. The condition increased to all but complete atrophy, and blindness in the affected eye.

It would seem that this was an example of the rare form of amaurosis which may follow loss of blood from the stomach, bowels, or uterus.

It is said to be characteristic that the dimness of vision does not come on until several days after the haemorrhage, and apparently there is no direct relationship between the extent of the haemorrhage and the severity of the visual loss. The most complete and permanent loss of vision is supposed to occur when the stomach is the seat of the haemorrhage, as in this case. Pallor or atrophy of the disc seems to characterize the later stages of the condition, but in some cases this was certainly preceded by neuritis as in the present example. The pathogenesis of the condition is still unexplained, but its occurrence in one eye only, as in the case quoted, shows that the lesion must lie in front of the chiasma. Von Graefe and Jaksch<sup>5</sup> believed that the blindness was due to extravasation of blood at the base of the skull and into the sheath of the optic nerve. Horstmann<sup>6</sup> attributed it to optic neuritis, Ulrich<sup>7</sup> to stasis in the retinal veins, and Theobald<sup>8</sup> to thrombosis of the central retinal artery, but neither of these explanations carries us very far.

Another rare form of optic neuritis came under my notice recently in the Maternity Hospital.

The patient, aged 26, was in the third or fourth month of her second pregnancy. She was admitted to hospital with her amenias, this condition ceasing a day or two after admission. At the same time great dimness of vision was noticed, and I

asked to see her three days later. The pupils were of medium size and moderately active to light. There was a large albinotic defect in the centre of each field and fingers could be counted with peripheral vision at a distance of about one foot. Ophthalmoscopic examination showed a rather unusual picture: a wedge-shaped temporal segment of each disc corresponding with the papillo-macular bundle being pale and swollen, the swelling invading the adjacent retina. After a further period of three days the vision was reduced to bare perception of light and the swelling of the discs was more prominent, while in the left eye one flame-shaped haemorrhage had appeared just outside the disc margin in the 2 o'clock position. In a few days even light perception was lost; further haemorrhages had appeared and the swelling was tending to invade the rest of the optic disc. Slight but definite reduction of the oedema followed a lumbar puncture. The patient died nine days after my first examination and the *post-mortem* examination revealed nothing which satisfactorily explained the cause of death.

Probably the optic nerve affection which has been most frequently reported in association with pregnancy is a chronic retrobulbar neuritis but Greenow, who discusses the question in the *Gräfe-Saemisch Handbuch*,<sup>8</sup> states that it may take the form either of an optic neuritis or of a retrobulbar neuritis. A Knapp reports three cases in which the discs are described as pale with blurred outline. I have found no record of a case in which the ophthalmoscopic picture resembled that in the one here described. The condition is usually attributed to the toxæmia of pregnancy, but the nature of the toxæmia is very little understood. The presence of albuminuria is not an essential factor. Miss Evans of Liverpool<sup>9</sup> read a paper giving the results of certain investigations into the cause of the toxæmic conditions of pregnancy—oedema, albuminuria, hypotæmia, accidental haemorrhage, jaundice, and eclampsia. Being disappointed with the results of biochemical research, she instituted bacteriological tests, and found coliform and other organisms in the urine of patients suffering from these toxæmic disturbances. In the case I have just described bacteriological examination was only carried out in the case of the throat, micrococci being found in the direct smear and staphylococci and streptococci in the culture. The urine showed a small amount of albuminuria on several occasions which may have been accounted for by the presence of pus. Fehling's solution was reduced on two occasions, and the fermentation test for sugar was only weakly positive. Bile was usually present, and diacetic acid and acetone were practically constantly found. The only other finding which might have some bearing on the optic neuritis was the presence during life of some evidence of disease of the ethmoidal and frontal sinuses. This was confirmed at the *post-mortem* examination but the rhinologist did not consider it at all likely that it had given rise to the optic nerve disease or that it was connected in any way with the patient's death.

Ever infirm out-patient work forces one to realize the difficulties inherent in the subject of optic neuritis for the conditions under which the work is carried on often make it difficult to obtain the completeness of investigation which these cases demand and many of them are under observation for too short a time to enable their immediate course and after-history to be traced. Nevertheless, one has to try in the course of the daily round to sort the cases of optic neuritis into their etiological groups and to seek for rational lines of treatment. As far as possible we follow up the investigation of the eye with primary tests: Wassermann test, examination of the ear, throat, nose and teeth, and investigation of the central nervous and other systems. In this connexion we have had the benefit of expert rhinological assistance and we are tempted to try to estimate the frequency and nature of the association of optic neuritis with disease of the nose and its sinuses and to determine how far operation on these structures is of value.

The difficulty of this aspect of the subject is demonstrated by the enormous amount of literature which it has already produced. It must be admitted that a great deal of this literature is of little value since conclusions have been based on material which has not been carefully investigated. This particularly applies to the many interesting reports of single cases which have shown striking improvement in vision after intranasal operation. We have all seen such cases. A young woman suffered from a unilateral blindness of acute onset. She has a papilloedema or retrobulbar neuritis, and there is evidence of nasal sinus

disease. Operation is carried out, and in a few days vision is restored. Undoubtedly, in many such cases the satisfaction of patient, oculist and rhinologist lends too much weight to the *post hoc* argument and the case is claimed as proof of the causal relationship of sinus disease with optic neuritis. Similarly, cases are reported where vision has been restored after removal of a septic tooth or of unhealthy tonsils. The weak point in these cases lies in the fact that so many of them belong to the type of optic neuritis which tends to rapid recovery without treatment, and that if their after-history could be traced some, if not many of them, would be found later to manifest signs of multiple sclerosis. But when all such unsatisfactory reports have been eliminated, the literature contains records of a vast amount of serious work on the subject. Unfortunately, even conscientious investigators have not yet succeeded in reaching anything like unanimous conclusions on these important problems.

- 1 What type of nasal disease gives rise to optic neuritis?
- 2 What are the clinical characters of an optic neuritis which has its origin in disease of the nose or nasal sinuses?
- 3 At what period is operative intervention called for?
- 4 What should be the operation of choice?
- 5 How does operation effect improvement or cure?

I cannot attempt to review the literature bearing on these questions, but may illustrate the difficulties of the subject by a few references.

Of the eight cases reported by Garin Young as benefiting by nasal operation two only showed any purulent secretion. Oskar Beck<sup>10</sup> examined the mucous membrane from the sinuses in successfully operated cases and found changes which suggested merely a serous catarrhal inflammation. He concluded that disturbance of ventilation of the sinus was the principal factor in causing the optic neuritis. Liebau<sup>11</sup> in clinical investigations found the optic nerve most often affected in congestive catarrhal nasal condition without polyp and without purulent secretion.

Many other authors report successful cases in which the sinus disease was "latent" that is, there was no clinical evidence of its existence, and nothing was revealed at operation. Opposed to this are the conclusions expressed by E. D. Davis,<sup>12</sup> who in analysis of fifty-four cases of optic neuritis sent to him for rhinological examination, found four in which there was nasal sinus suppuration. They were unilateral, of some duration and rapid and permanent improvement in sight was obtained in three, the fourth being already in the atrophic stage. Twenty-three of the cases presented no evidence of nasal trouble, and did not come under either multiple sclerosis or any other definite category, and the six cases were acute in onset and recovered spontaneously, that is to say, in the hands of another observer they might have been dealt with as cases of latent sinus disease, and credit for the recovery given to operation. Onodi's successful cases also showed gross suppuration of ethmoidal and sphenoidal cells.

The characters of the optic neuritis vary a good deal in different reports, sometimes being described as a retrobulbar neuritis, in other cases as a visible papillitis, it may be even with haemorrhage and retinal exudates. On one point there is a fairly general agreement—namely that there is no characteristic defect of the visual field which enables optic neuritis of nasal sinus origin to be distinguished from other forms of optic neuritis. But, as Traquair<sup>13</sup> points out, a careful investigation of the visual field may enable us to exclude pituitary tumour and other conditions which do give rise to characteristic changes in the visual fields. This, of course, is not always possible. The acute cases, for example, are usually seen by the oculist at a stage when the affected eye is so blind that no delicate field tests can be carried out, and the character of the scotomata can only be worked out when the condition has definitely begun to recover. Of the cases of rhinogenic optic neuritis which I have had under my care at least one-half showed some degree of papilloedema, accompanied in several by a few small haemorrhages near the disc. Most of these were unilateral and acute in onset. The

conditions found by the rhinologist included septal deflections, turbinal hypertrophy or granularity, and disease of the ethmoid and sphenoid cells. Operation was performed about three weeks after the onset of the visual defect, and improvement began in about one week from the date of the operation. Vision was almost, if not quite, completely restored, but the affected disc remained a little pale.

One such case, which was not submitted to operation, seems to illustrate the influence of a "chill" in determining the onset of the optic neuritis. The patient, a woman of 49 received a bad drenching while berry-picking. She continued at work with severe pain above the left eye. In a few days the left eye went dim, and a week later the right eye also. When seen, right vision was "fingers," and left vision "no light perception." The discs both showed a moderate degree of swelling. For some days matters got worse, the swelling of the discs increased, and a haemorrhage appeared on one. Vision was reduced to doubtful light perception in both eyes. Recovery was very gradual and incomplete, a large relative central scotoma, most profound for colours, remained. In about a month the discs were normal but the best visual result obtained was 5/36 in the right eye and 5/60 in the left. Nasal examination had revealed deflection of the septum, granularity of the middle turbinal, and unhealthy mucous membrane in the region of the right and left ethmoids, but, as I have mentioned, no nasal operation was performed.

Very few of my cases of retrobulbar neuritis, whether acute or chronic, have shown evidence of nasal sinus disease, and in the absence of clinical signs nasal operation has not been recommended. The acute cases have, of course, made a good recovery under medicinal treatment.

The most satisfactory example of the benefits of nasal operation was a case of retrobulbar neuritis of eight months' duration, with large central or caeco-central scotoma in both eyes, the vision of the right being 6/36, and that of the left 6/60. Septal deflection, enlarged inferior turbinates, and ethmoidal suppuration, were found and rectified by operation, and recovery began within a month and was complete in about three months. Slight temporal pallor of the discs remained.

A case which I have followed for two or three years with a good deal of interest was that of a man of 27 who when first seen, presented the history and signs of acute retrobulbar neuritis in the right eye, which had been painful and nearly blind for three days. When seen the right eye had merely light perception and the edges of the disc were hazy. He stated that the same occurrence had affected the left eye five years earlier, but with almost complete recovery. Vision in the left eye was 5/12, but the disc was in a condition of simple atrophy. The rhinologist found definite signs of ethmoiditis on both sides, and operated. Within a month vision in the right eye was 6/6, but thereafter it gradually failed again in the course of two years to 6/18. Meanwhile the left eye showed repeated variations between 6/4 and 4/60, but the puzzling feature of the case was the ebb and flow of the visual acuity along with steadily increasing pallor of the optic discs. Moreover, although two further nasal operations were carried out, improvement in vision did not seem definitely related to these procedures. I was tempted to look upon this as a case of retrobulbar neuritis of sinus origin, and there is no doubt that operation on the sinuses was justified, but I have always felt apprehensive that signs of multiple sclerosis will develop, though none have shown themselves during the period of observation.

Multiple sclerosis probably accounts for a larger proportion of the cases of retrobulbar neuritis than does disease of the nasal sinuses, but since optic neuritis, like other symptoms of this disease, may be an isolated phenomenon, we may have to wait a considerable time before the diagnosis of multiple sclerosis is confirmed by the appearance of other nervous manifestations.

H. Henson of Hamburg<sup>12</sup> emphasizes the importance of the duration of the central scotoma in retrobulbar neuritis due to multiple sclerosis. He says that multiple sclerosis may cause either a transient scotoma lasting three or four weeks and ending in complete recovery, or it may cause a central scotoma which lasts longer and does not show a tendency to recover, but the retrobulbar neuritis of the latter type never lasts more than three months without the appearance of other nervous signs of the disease.

The case which I have just referred to, and another which concerns a man of similar age in whom no signs of nasal sinus disease or of any other organic disorder have appeared in the course of three years' history, lend me to doubt the reliability of this dictum. It seems to me that we are still in need of more definite criteria to differentiate these varieties of optic neuritis from one another.

On the question of the operative treatment of these cases I am inclined to adopt a conservative attitude. The universally admitted fact that the great majority of cases of acute retrobulbar neuritis recover without interference does not preclude one from believing that such cases are

due to nasal sinus disease, but it is quite a sufficient argument against operation in the earlier stage. Moreover, if it is true, as van der Hoeve<sup>14</sup> says, that in rhinogenic retrobulbar neuritis degeneration of the nerve does not occur, and that recovery can be obtained, even if blindness has been of some duration, there is the excuse for immediate operation, although, if the condition is such that the rhinologist considers operation called for on other grounds, there seems no reason why this should not be carried out. Since, in most cases, retrobulbar neuritis, whatever its origin, recovers within five or six weeks, and the retrobulbar neuritis of a multiple sclerosis is a transient phenomenon, it is usually so safe to recommend medicinal treatment for a period of six to eight weeks. At the end of that period if improvement has not set in and the condition of the nose is suspicious, operation is justified. I have experience of cases in which sinus operations have been carried out in the absence of clinical signs, but many convincing cases of the kind have been reported. Certainly any radical treatment of the interior of the sphenoidal sinus in these cases is to be deprecated, at the most "ventilation" of the sinus is justified, and it may be enough to carry out some simpler procedures, such as submucous resection of the septum, or removal of the end of a turbinate bone which is blocking the sphenoidal ostium. The rationale of the treatment in so-called "latent" cases has been much disputed, but it has been suggested that the benefits may be merely the result of local "bleeding," and these of us who are familiar with the effects of blistering, leeching, and other vasomotor reflex phenomena will not deny the possibility of similar results from minor operations in the nose, or even from the application of adrenaline and other drugs to the nasal mucous membrane.

#### DISCUSSION

Professor J. VAN DER HOEFF (Leyden) maintained the view since the origin of the affection of the optic nerve in high intracranial pressure was not inflammatory this condition should be distinguished from other types of optic neuritis. He added that ophthalmologists ought to be thoroughly conversant with x-ray photographs of the skull. During the procedures of decompression of the skull and lumbar puncture, ophthalmoscopic examinations of the patient should be made. An early operation should be advised if increased intracranial pressure if the visual power was to be retained, since if there was delay decompression might even hasten atrophy. The origin of retrobulbar neuritis was manifold, and the relative percentages of the several causes of the condition varied in different countries and cities.

Dr. H. M. TRAQUAIR (Edinburgh) emphasized the need for a revised terminology in optic neuritis, and suggested the term "plerocephalic oedema" for the swelling of the optic nerve in increased intracranial pressure. "Papillary oedema" was an unsatisfactory term in this connection since oedema of the disc occurred often apart from increased intracranial tension. He divided optic neuritis into two groups—those of the plerocephalic oedema type and those cases of optic neuritis in which an inflammatory lesion of the nerve or its sheath was diagnosed. He thought that rhinogenic optic neuritis should be confined to cases with an actual inflammatory focus in the papilla, while atrophy should be provisionally included as a form of optic neuritis.

Dr. GEORGE YOUNG (Colechester) described a case of plerocephalic oedema in a young woman who had been lying down by a motor car. She was unconscious, had widely dilated pupils, and was found by a motor car.

pupils low temperature, slow pulse and appeared to be moribund. Hemiplegia was present but there were no signs of fracture of the skull both eyes had extremely choked discs. After trephining over the posterior Kronlein point and opening the dura, the patient obtained relief. The choking of the discs and the papilloedema disappeared, and she recovered health and full vision.

SIR J. H. PARSONS (London), was one largely responsible for the introduction of the term "papilloedema" deprecated the further complication of the nomenclature of these conditions. It was true that papillitis manifested itself first as a slight oedema, to be followed later by cellular infiltration, but the same condition was produced by inflammation in other parts of the body and the distinction of papilloedema from papillitis or optic neuritis is parallel to the use of the general terms "oedema" and "itis" (indicating inflammation). He concluded that Prof. or Ronne thought that many cases of retrobulbar neuritis were associated with plaques in the optic nerve containing degenerated medullary sheaths with many intact axis cylinders as in the well known lesions of disseminated sclerosis. This was a very illuminating suggestion, but it must be remembered that the symptoms of retrobulbar neuritis often preceded any pathognomonic signs of disseminated sclerosis by intervals which might extend to several years.

DR. DE SCHWEINITZ (Philadelphia) referred to Koeppe's method of distinguishing choked disc and optic neuritis by means of the slit-lamp especially in the early stages of these conditions. Although the test (the absence of "inflammatory cells" in the first instance and their presence in the second) was not universally accepted it deserved to be used more often. Although he fully recognized the difficulty of making a differential diagnosis in certain cases of optic neuritis and choked disc he believed that a clinical distinction should be maintained papilloedema (choked disc) indicating a condition in which oedema was the dominant factor, and optic neuritis one in which an inflammatory process was concerned. Clinically he was guided by Marcus Gunn's description of the six stages of choked disc (papilloedema). The surest method of preventing the end-result of choked disc—namely atrophy—consisted in a release of the increased intracranial pressure to use Victor Horsley's expression, by an operative procedure, usually so-called palliative trephining other things being equal. How long an operation should be deferred must depend upon frequent testing of the acuity of vision and charting the visual field especially the size of the "blind spot" or more accurately that of the increasing size of the peripheral amblyopic zone. He agreed in deprecating operative intervention with relation to the paranasal sinuses and was convinced that infected sphenoidal disease was a definite etiological factor in many cases of retrobulbar neuritis and more frequently the case than the observations in England would seem to indicate. He was in accord with Professor van der Hoeve that in certain cases after due trial of conservative measures operation was required, which should be performed by one skilled in this type of operative work. He did not refer to acute retrobulbar neuritis with its well known visual field disturbances and other clinical signs, which depended on various causative factors and was often a self limited disease.

DR. W. H. WILMER (Baltimore) agreed that in certain chronic optic nerve inflammations greater emphasis was laid upon the sinuses in America than in other parts of the world. The ordinary x-ray photograph of the sinuses often failed to show pathological conditions in the cells around the optic canals. At the Oxford Congress Dr. Tyson had exhibited a picture of the optic canals of a man who was gradually losing his sight from a post-neuritic optic atrophy in spite of the facts that all recognizable sources of infection had been excluded or removed and that the sphenoid and ethmoid cavities had been opened four times. The picture showed the complete removal of all diseased cells except those just around the optic nerves. Dr. Wilmer had seen this patient and doubted whether the removal of the diseased cells could be removed without injury to the optic nerves themselves. Yet in the absence of any blind-

ness was inevitable, and further operative procedure seemed to be justifiable. In some cases of chronic retrobulbar neuritis the cottony appearance and vision returned after the removal of several possible toxic sources. It was often impossible to say which was the cause of the trouble.

SIR WILLIAM LISTER (London) referred to the form of papilloedema found during the war in cases of injuries to the head or of concussion. He thought that there was nothing characteristic about the appearances. There were the three primary signs—swelling of the disc, blurring of the edges, and fullness of the veins. There was very slight swelling and it could be recognized very much more easily by the bending of the vessels as they passed off the disc than by measurement with the ophthalmoscope. This pointed to the condition having been due to a very slight intracranial pressure.

DR. WILDER (Chicago) quoted the statement of Dr. Paterson that around the eye there was frequently evidence of the presence of oedema when inflammation was not present though it might be impending. Such oedema, which began round the orbit might be equally of inflammatory nature, though the stage of inflammation had not been reached. It seemed that in some of these conditions there were plaque formations such as Professor Ronne had described which might be the beginning of inflammatory oedema and might ultimately result in severe disturbances. In many cases the inflammatory oedema lasted long enough to produce definite trouble, this also suggested that if it was very transitory recovery would be rapid, if it continued for some time a degenerative condition might ensue. In some operations upon the sinuses the results were so pronounced and startling that there must have been some connexion between the sinuses and eye condition. With definite inflammation and clear evidence that there was some infection of the sinuses operation became justifiable.

SIR GEORGE BRANT congratulated the office bearers on the choice of subject for discussion. Optic neuritis was far from being a topic which justified the rigid maintenance of fixed opinions. It was necessary to keep an open mind, and to be ready to accept new ideas when presented.

DR. J. V. PATTERSON in his reply stated that he did not take up the position that intranasal disease was never a cause of retrobulbar neuritis. In his opinion in ordinary cases of retrobulbar neuritis adequate nasal cause was seldom present.

DR. ROSS, referring to a remark made by Dr. Paterson regarding vitreous opacities in optic neuritis said he had examined a great number of specimens in cases of lesions of the optic nerve and had never found inflammation present anterior to the lamina cribrosa. Any change occurring in front of the lamina was always an oedema.

## VITAMIN A DEFICIENCY AND UROLITHIASIS \*

BY

PROF. OF E. G. VAN LEEPSUM,  
Netherlands Institute of Nutrition Amsterdam

SOME years ago Osborne and Mendel<sup>1</sup> drew attention to the frequency of calculi in the urinary tract of rats fed on rations deficient in vitamin A. In 857 sections they found calculi 81 times. "In every instance," they wrote, "where calculi developed the animals were without an adequate source of the fat-soluble vitamin." Later, in 1920, on the occasion of a vitamin symposium of the New York Medical Association, Mendel said:

When it is recalled that phosphatic calculi deposited in a neutral or alkaline urine which in turn frequently owes its reaction to bacterial decomposition are found extensively among peoples living for example in the tropics and the Far East on diets quite unlike the mixed regime of most Americans and Europeans the possible reaction of the calculi to dietary factors is at once prominently suggested.

A paper read at a joint meeting of the Section of Pathology and Bacteriology and of Comparative Medicine at the Annual Meeting of the British Medical Association, Edinburgh 1927.

On this McCollum<sup>2</sup> wrote

"Osborne and Mendel observed calculi of calcium phosphate in the urinary tract in 91 [read 81] animals among 857 necropsies, 43 per cent of these had not had a satisfactory supply of vitamin A. In McCollum and Simmonds's experience calculi have occurred so frequently in animals whose diets contained an abundance of this factor, but were faulty in other respects, that it would seem to be the results of general debility rather than lowered vitality brought about by specific cause"

The contradiction in the observations of the experimenters led me to control the records of the rats of the laboratory of the Netherlands Institute of Nutrition. I have examined 886 rats, picbalds and albinos, of which 405 were males and 481 females. Among them are 241 rats (see

Diet	Number of Rats	Cases of Calculi	Other Lesions		
			Haematuria	Cylindruria	Xerophthalmia
Adequate vitamin A	211 { 108♂ 133♀ }	0	0	0	0
Deficient vitamin A	645 { 297♂ 348♀ }	130♂ 67♀	46	12	92

table) which certainly never suffered from vitamin A deficiency. Their diet consisted in wholemeal bread, raw milk, butter or cod-liver oil, raw carrots or cabbage, and, now and then, some cheese and spinach or lettuce. In none of these 241 rats (108 males and 133 females) were calculi found. Hence the conclusion does not seem too bold that in healthy, adequately fed rats calculi do not appear, or are at any rate rare.

Among the other 645 animals (297 males and 348 females) 197 cases of calculus were found—namely, in 130 males and 67 females. These rats had been fed on an A-deficient diet. Among them were some that were fed on a rickets-producing diet. That all these rats suffered from vitamin A deficiency was shown by clinical examination. They grew little, and the mortality among them was great. In a number of those I examined the oestral cycle was disturbed. There were also many cases of xerophthalmia. That this eye disease did not occur still more frequently must be attributed to the short life of many rats. The search for calculi was made with care. In all cases the pelvis, the ureters, and the bladder were examined, and, to make quite sure, the bladders which were apparently without calculi were also investigated microscopically. In this way it was possible on several occasions to find concretions invisible to the naked eye. X-ray photographs were taken of many of the rats.

That calculi are more frequent in males than in females has its natural explanation, already given in the Hippocratic book *De Aere Locis et Aquis*—namely, that the urethra of females is short and wide.

Most of the calculi consisted of calcium phosphate or of a mixture of calcium phosphate and calcium oxalate. Calcium oxalate concretions occurred in rats on McCollum's rickets-producing diet. A number of rats suffered from haematuria. However, this did not occur so often as might have been expected, considering the frequency of the calculus. Though probably caused by the lack of vitamin A, it is yet of less frequent occurrence than calculus, and is not directly connected with it, for in many cases of haematuria there were no calculi, while in many cases of calculi in the bladder there was no blood in the urine.

Contrary to all expectations, obvious cystitis was rare. As a rule the urine was clear and its reaction to litmus was acid. In most cases of calculus, on microscopic investigation the mucous membrane proved to be normal and the surface layer of the epithelium intact.

Calculi may soon appear in case of vitamin A deficiency, the production of calculi in three or four weeks proved to be very common. Several times I found formations in the urine, in shape resembling crabs, they were straight or bent crystalline cylinders of calcium phosphate or oxalate. This discovery led me to examine the kidneys, and I found that, in vitamin A deficiency, lime deposits in the tubules are frequent, not to say constant. These lime deposits are found throughout the kidney, especially

in the tubules, but never in the glomeruli. According to the shape of the tubules, they are straight, bent, or sinuous.

Altogether I examined 254 rats with regard to their kidneys, 76 had had a satisfactory supply of vitamin A, and 178 had suffered from vitamin A deficiency. Of the 76 rats, 10 had lime deposits in their kidneys, but these deposits were very small in number, one, or at most two, to a section. Hence I believe that with healthy, adequately fed rats lime deposits of any size in the kidneys may be said to be exceptional. On the other hand, calcium deposits in the tubules were almost constant in the rats suffering from deficiency of vitamin A, of 178 rats deposits were found in 158 (87 per cent), whereas there was a frequency of calculi in the bladder of only 35.4 per cent.

As a control I first extirpated one of the kidneys from a number of rats on an ordinary diet, and then withheld vitamin A from their food. I then, after some time, killed those which had not already died from the consequences of the operation or some other cause. In 14 rats which died within three to fifteen days after the operation there were no lime deposits in the extirpated kidney nor in the other one, 9 other rats fed in the same way also had no lime deposits in the extirpated kidney, but in 7 of them, after more than twenty days of vitamin A deficiency, I found deposits in the remaining kidney. These lime deposits form quickly, in one case of deficiency in vitamin A they had been formed in thirteen days.

From what has been said above it may be concluded that in rats there is without doubt a connexion between deficiency in vitamin A and the formation of phosphatic calculi.

It is known that absence of the fat-soluble vitamin from the food causes typical changes in the epithelium of the mucous membranes—for example, keratinization, witness the xerophthalmia and the lengthening of that stage of the oestral cycle characterized by the horny cells. Probably such a morbid change of epithelial cells of the tubules gives the impulse to the deposition of lime, which deposition, once liberated, grows to larger concretions in the bladder.

## EFFECT OF EARLY INDUSTRIALISM ON THE HEALTH OF THE COMMUNITY

BY

MABEL C. BUER, D.Sc. (Econ.),  
Lecturer in Economics, University of Reading

THE popular view is that the effect of industrialism on the health of the community was necessarily bad, but the fact is that the population of Great Britain grew at an unprecedented rate during the period 1760-1860. To account for this, an increase in the birth rate was postulated; there is, however, no evidence for this, and definite evidence for a decrease of the death rate. An estimate of the death rate for England and Wales in the middle of the eighteenth century shows that, on a rough average, it was 35 per 1,000. In the year 1815 it had been reduced to about 20 per 1,000. In the middle of the eighteenth century the death rate in London and other large towns was 50 per 1,000, while in 1815 the death rate in London was about 30 per 1,000. These figures give very little support for the contention that economic advance was at the expense of health. The main part of the population in the middle of the eighteenth century were living in comparatively isolated rural communities, in which the death rate is usually very high. It is not primarily a hot climate which is responsible for diseases like plague, but the lack of hygiene, along with the uncertainty of food supply. Plagues were frequent in medieval Europe, and scurvy certainly and rickets probably were present. The towns were without the elementary sanitation, overcrowding was rife, and the

## ABNORMAL DEVELOPMENT OF BLADDER IN A NEWLY BORN INFANT

THE details of the pregnancy and confinement of the mother of the infant whose case is recorded below I have been unable to obtain, except that it apparently was a normal nine months' pregnancy. The abnormality, however, is a very unusual one.

Externally the abdomen was an enormous size there was no trace of an anal opening, male external genital organs were present. The fluid which had caused the distension of the abdomen was lost during the confinement and six pints of fluid were required to re-distend it to its original condition, so that a photograph might be taken. On opening the abdomen an enormous cyst was found to occupy the pelvic, right and left lumbar, and subphrenic regions. A kind of diverticulum passed upwards, behind and to the right of the coils of intestine, which were smaller than normal for a full term infant. The lower end of the large intestine was greatly dilated with meconium, and it was adherent to the upper and back portion of the left side of the cyst, the gut, however, had no opening into it, but ended blindly. The right kidney could not be distinguished, but its position below the suprarenal gland was indicated by some thickened tissue at the upper end of an enormously dilated ureter. There was a greatly dilated left hydronephrosis with only a small amount of kidney tissue persisting. Its ureter was enormously dilated like that of the right side, and the two ureters passed downwards intramurally in the wall of the cyst. The interior of the cyst presented the appearance of a distended and greatly hypertrophied bladder, marked by numerous diverticula and ridges due to the hypertrophy of the underlying muscle. The ureters opened by two exceedingly small orifices which were by no means easy to find. The lower or pelvic portion of the cyst was perfectly smooth, and there was no trace of an opening from it to represent a urethra. The testes were smaller than normal and lay on the lower part of the dorsal surface of the cyst. They were connected to it by short, well developed vasa deferentia which crossed transversely and opened into a shallow diverticulum of the cyst. There were no seminal vesicles present.

It would appear that this "cyst" was an enormously distended cloaca, and the shallow diverticulum—which was smooth and had a wall thinner than the rest of the "cyst" and into which the vasa deferentia opened—that part of the urogenital sinus which should normally form the prostatic portion of the urethra.

The condition of the bladder in this case is most unusual, and I have been unable to trace any similar case recorded. It would appear to be caused by the absence of any outlet from it for the flow of urine, and as there was such an enormous accumulation of urine present it raises the interesting question as to the period when the kidneys began to secrete.

### LEGAL PERILS OF THE DOCTOR

At the meeting of the Hunterian Society, held at Cutlers' Hall in the City of London on November 7th, a discussion took place on "The legal perils of the doctor." Mr. MORTIMER WOLFE presided, and among those present was Mr. Justice McCARDIE, but he took no part in the discussion.

Dr. JAMES NEAL (general secretary of the Medical Defence Union) said that the doctor, in addition to the legal obligations of the ordinary citizen, had certain obligations imposed upon him under a number of statutes, and certain others by the traditions of his profession and the Warnings Notices of the General Medical Council. It was strange that the teaching of law should have no place in the medical curriculum, in view of the many respects in which a doctor was open to legal action. A doctor was always at the mercy of an hysterical or insane patient, and very often, in order to avoid publicity, he was tempted to settle by the payment of money a claim which ought never to have been made. A patient was entitled to recover damages for negligence—fortunately not for failure to cure—and negligence was a vague, indefinable thing, not governed by statute, although the subject of judicial rulings from time to time, it was a matter of fact rather than of law, and therefore a matter for a jury. Although the bench had displayed a tolerant, even a lenient, attitude

towards the medical profession, it was by no means certain that a jury would take the same view. Turning to certification, Dr. Neal said that this bristled with perils. Every medical man should take scrupulous care to certify only to such facts as were within his personal knowledge. With regard to the British Medical Association's proposal for strengthening Section 330 of the Lunacy Act by the appointment of assessors to sit with the judge, he did not know to what extent this would serve to protect the certifying doctor, and there would still remain the danger that action might be taken against the doctor on the ground that the statements in the certificate were a libel on the patient. Some similar protection to that accorded to a witness in a court of law should be granted, though he would not desire such protection to be made absolute and thereby to screen the doctor who had acted carelessly or in bad faith. Dr. Neal deplored the fact that medical men who had successfully resisted in the courts allegations against their professional competence or care should be mulcted in large costs owing to the fact that the plaintiff had proved to be a man of straw.

Dr. RUSSELL said that he had been in the habit of looking on the doctor as the high priest of civilization, in control of the actions and liberties of the people. But the doctor had not got the protection accorded to the high priest, nor had he the sacrosanct character attaching to the *tribuni plebis* in Roman times, he remained a citizen to be "shot at." No society of medical men would desire that doctors should be exempt from penalty if they had been reckless or negligent in the treatment of their patients. The simple rule that medical men should follow was honestly to do their best for every patient with the utmost skill at their command. He did not see how any adequate training in law could be introduced into the already overcrowded medical curriculum, as Dr. Neal seemed to desire, and a partial knowledge of law might be worse than ignorance in leading men astray. Nor did he understand a suggestion by Dr. Neal that doctors should be exempted from the payment of costs in actions in which they had been successful but in which the other party had proved to be a person of no substance. That was a misfortune from which many litigants, not doctors alone, suffered. Lawyers could not consider a question merely from the point of view of one class of the community. He did not know on what grounds doctors were to be made an exception, nor from what source the costs were to come. As to certificates, the immunity given to a *visa voco* witness in the law courts, which was granted in the interests of the administration of justice, could scarcely be extended to the certifying doctor. There were undoubtedly cases in which doctors were casual in their matters, sometimes reckless, occasionally, it might be, not bona fide, and no one wished to protect a medical man from the consequences of his action in such cases, so that there could not be complete immunity. He was not surprised that doctors were rather afraid of certifying at the present time, but the legal members of the Royal Commission on Lunacy were unable to devise anything better than appeared in the report. As for the suggestion that there should be medical assessors, he did not quite know what such persons were to do. Owing to old historical traditions naval assessors sat with the judge in admiralty actions, but that was the only case in which the judge was supposed to be unable to understand evidence and to need someone to interpret it for him. A strong case would have to be made out for any extension of that practice, and if medical assessors, why not assessors in other cases involving special conditions of skill?

Mr. HERBERT WATKINSON said that as president of the Medical Defence Union he had known actions which had all substance to be brought against doctors, and yet the all solicitors for the plaintiff never failed to get medical men to go into the witness box to testify against a professional colleague. Nor were the medical men who gave evidence under such circumstances obscure members of the profession, frequently they were leading members. Often the evidence they gave would never be recognized by their professional colleagues if those colleagues were on the jury. He instanced a case against a medical practitioner, in which he and other medical witnesses who gave evidence con-

the doctor's behalf thought might well be laughed out of court, but in which an eminent surgeon appeared on the other side. It was just as well that that eminent surgeon said in the witness box was not said by him when he was sitting for the Fellowship examination of the Royal College of Surgeons! Sir Herbert Waterhouse went on to deal with cases of blackmail, major and minor, the latter comprising those cases in which, when the patient was confronted with the doctor's bill, he made persistent allegations of negligence as an excuse for not paying. A doctor accused of negligence should, for the sake of his profession, fight the case out.

Mr RAYNER GODDARD, speaking from a quarter of a century's experience at the bar, said that it might be no consolation to the doctors, but nevertheless it was true, that members of every profession (the bar excepted) were open to action for negligence. But when the number of doctors on the *Medical Register* was borne in mind, together with the number of consultations which must take place daily and hourly, and was compared with the small number of actions brought against medical men, he did not think that the peril of legal action need haunt the doctor's sleep. With regard to the point raised by Sir Herbert Waterhouse about opposing evidence from other members of the profession, he pointed out that the medical profession, like every other, had members who were incompetent, unskilful, and negligent and should a person be treated by one of these to his grave and avoidable injury, it would be a shocking thing if on taking action against the practitioner, he could not find a medical man to give evidence for him simply because the profession was in a clique in which no doctor must give evidence against another. Doctors were, as a rule very loath to give evidence against another, and a lawyer might be pardoned in advising a client to proceed if he found that he was in a position to call other doctors. The speaker thought it incumbent upon a doctor, if he honestly believed that another practitioner had inflicted a great wrong upon a fellow citizen to assist the ends of justice. As for that palladium of British liberties the jury, he noted that the trend of recent legislation was to take cases away from juries but his own experience was that juries were by no means prone to take views antagonistic to doctors. He also made a suggestion for lunacy certification, that no person should be confined in an asylum unless his case had been considered by a panel of three medical men and that it should not be possible to bring any action against a doctor who in good faith referred a case to such a lunacy panel. In cases of emergency where the patient showed homicidal or suicidal tendencies the doctor might be allowed to give an emergency order for restraint to hold good for a few days until the case could be brought before the panel.

This concluded the speeches of the "openers" but as it was now 11.15 p.m. not even the staying power of the Hunterian Society was equal to a prolonged general discussion. Dr THOMAS GUNN dealt with some points, urging that if a judicial authority could not be found to take the responsibility for certification some other way must be sought and that it was unfair that medical men should be under this peril when at the same time they were bound to perform a public duty. Dr PERCY SMITH did not see why the medical certificate should not be regarded as a statement on oath for the purposes of evidence in court. He said that it was by no means true that all patients resented detention; he was accustomed to receive grateful letters from patients, now discharged for whose detention he had been responsible. Dr NEAL briefly replied.

## PSYCHIATRY AND THE REPORT OF THE ROYAL COMMISSION

THE presidential address in the Section of Psychiatry of the Royal Society of Medicine was delivered on November 8th by Dr R. LANGDON DOW, whose subject was "Psychiatry and the Report of the Royal Commission."

Dr Langdon Down reminded the Section of the circumstances in which the Commission was set up, and of the

general character of its report. Sometimes the reports of Royal Commissions were laid by on the shelf, but this was unlikely to happen in the present instance because the matter called urgently for legislation, which the Minister of Health had indeed promised would be forthcoming in the new year. As to the general value of the report there could be no question. It gave a decisive answer on matters previously in debate. It laid down in clear terms the principles which should guide the Legislature in dealing with the insane, adopting in the main the principles which had been urged by the medical profession, and it repudiated the notion that there existed any substantial abuses. On examining the report in detail, however, Dr Langdon Down found certain matter for criticism, especially in the procedure recommended for placing involuntary patients, when there was a prospect of recovery within a short time, under care and treatment without recourse to full certification. His objection to the Provisional Treatment Order by which it was proposed that this should be done was that it contained the judicial intervention and formality which was the real objection in certification. The term "certification" referred comprehensively to the whole procedure of a reception order made by a magistrate who had before him one or two certificates signed by medical practitioners. What the patients and their friends objected to in certification was not the expression of medical opinion or diagnosis on the certificate, but the whole procedure which invested the certificate with the forms of law, and inevitably suggested a penal aspect. A German medical practitioner, writing about the working of the English law in this respect, stated that he had found it difficult to understand the introduction of what was apparently a penal side into this procedure, and asked if this did not cause confusion. The essential fact in certification which made it abhorrent to those faced with it was the share taken by the representative of the law.

The Provisional Treatment Order proposed by the Royal Commission, strangely enough, accentuated the duties of the justice and elaborated them in various ways. It was, in essence, the very procedure of certification over again. Such a procedure was in no way calculated to approximate the treatment of mental to that of physical disorder. It was true that the doctor's signature was to be attached to a "recommendation" instead of to a certificate but could it be supposed that to style a certificate a "recommendation" would do anything to allay objections? Nor would it be more acceptable because it was limited to a month and was termed provisional. The failure of the Commissioners to bring their proposals into harmony with the principles laid down in their own report was much to be deplored. They had assumed as a self-evident fact that the only proper safeguard was the judicial authority, and that his intervention before treatment was undertaken was a vital principle of universal application. In this the Commission was deferring to a public prejudice, instead of which it might be expected that a Commission would endeavour to guide public opinion. But it appeared from the proposals that, while changes might be made in various directions, no change must be suffered in respect of the legal formality which the public would look upon as a safeguard. Yet even under the present lunacy laws there were various departures from this principle. For example, a lunatic might be detained in the workhouse for fourteen days on the certificate of the medical officer of the institution. By an accumulation of periods under different sections of the Act as long a time as twenty-three days might elapse before the justice was called upon to make a summary reception order, and it was not suggested that abuses had in fact occurred through these extra-judicial periods of detention. In Scotland also the principle had been departed from, without any evil results. It was admitted on all sides that adequate safeguards were necessary, but the unsatisfactory form of the proposals offered in the report was the result of assuming that the judicial authority was the only proper safeguard. In fact the intervention of the justice was the one safeguard which tended to be somewhat illusory in practice. The judicial authority was the one party to the procedure on whom apparently no real responsibility fell. The real and

effective safeguards depended on the vigilance and experience of the Board of Control and on the trustworthy and responsible way in which the medical share in the work had been done. If the justice was to be brought into this Provisional Order procedure it should be at the request of the patient, when his function would be clearly defined, and his decisions, being invited by the patient and supported by the medical evidence he would be entitled to call, would be on the merits of the case.

Dr Langdon-Down suggested tentatively a proposal for avoiding these objections. All patients requiring mental treatment should be dealt with, in the first instance, either by a voluntary application or a preliminary authorization for treatment, the latter to be made by a relative, friend, or public official, supported by two medical opinions to the effect that the patient required treatment for his mental condition in a place recognized for such a purpose, and the admission of the patient for treatment should be reported to the Board of Control within seven days. The patient should be given the right to call in a judicial authority if he considered that he ought not to be placed under treatment, and if the justice decided, after taking medical opinion, that the patient should continue under treatment, he would make an order accordingly. The preliminary authorization would be valid for fourteen days, but capable of extension. It would have the advantage over the Provisional Treatment Order, which retained the judicial procedure while actually weakening the medical safeguards, that it emphasized primarily the need for treatment rather than the need for detention, and did not complicate and confuse the procedure by a hopeless attempt to classify cases for this purpose by prognosis. It was only an extension of the present Urgency Order or the proposed Emergency Order, making its duration the more useful period of fourteen days instead of seven, and therefore it could not be taken to contravene any vital principle of law or public policy.

Turning to the risks under which the certifying practitioner laboured, Dr Langdon-Down said that under the law as it stood the intervention of the justice added no safeguard to the doctor, and therefore the elimination of this authority would add nothing to the doctor's risks. There was little or no dispute that the whole legal position of the medical practitioner in regard to the risks which confronted him in certifying the insane involved grave injustice. This was reaffirmed by the Royal Commission, which sought to ameliorate the position by transferring the burden of proof as to carelessness or bad faith. But even that proposal, as it stood, might fail to give the required protection unless the further proposal were adopted to strengthen Section 330 by appointing an independent medical assessor to sit with the judge in these cases. With this addition the doctor would have fairly substantial protection. Dr Langdon-Down then dealt with the question of witness-status, and the practical difficulties which were in its way, and he mentioned the remarks of Mr Justice McCaigie, made since the report of the Royal Commission was issued in delivering judgement in the case of de Freville v Dill, when the judge suggested that the cause of the detention might be, not the doctor's certificate, but the justice's order. In that case action would lie, not against the doctor, but against the justice, or, in the procedure just outlined, against the person who made the preliminary authorization. The profession and public were governed, however, not by Mr Justice McCaigie's views, but by the judgement he had to deliver, and by the law as commonly interpreted, and the doctor stood in a very hazardous position. It ought not to be necessary for some unfortunate victim to have to carry his case to the House of Lords. The profession had the right to ask that the law on this matter should be just and unequivocal. If there was doubt about interpretation, why should not the matter be cleared up forthwith by the House of Lords appointing, if necessary, a panel of judges as it did once before, in the McNaghten case?

Sir ROBERT ARMSTRONG JONES proposed, and Sir MAURICE CRUICKSHANK seconded, a vote of thanks to Dr Langdon-Down. The former said that he was unable to agree to the proposal to eliminate the justice.

## THE PRESENT POSITION OF SPINAL ANAESTHESIA

At the meeting of the Section of Anaesthetics of the Royal Society of Medicine on November 4th a discussion took place on the present position of spinal anaesthesia.

Dr CECIL HUGHES, president of the Section, in a brief introduction, said that the method of spinal anaesthesia had now been in use for over a quarter of a century, many papers had been published on the subject, embodying observations on thousands of cases, and the time had come to assess the value of the method as a routine procedure. The mortality was very slight, and such deaths as had occurred could mostly be attributed to the serious condition of the patient at the time, to an admittedly bad choice of anaesthetic, or to an overdose. He gave a synopsis of the recent papers on the subject, and then described his own technique, in which he used 5 per cent. stovaine, with 10 per cent. sodium benzoate and caffeine citrate, in distilled water, in 2 ccm. ampoules. He preferred to combine with this method a light degree of general anaesthesia, sometimes so light that consciousness was scarcely abolished. He avoided the method in cases where there was low blood pressure to begin with, myocardial degeneration, or spinal trouble. The class of operations most suitable for spinal anaesthesia were those on the lower abdomen, and he thought that in difficult pelvic operations, particularly urological and gynaecological, the use of spinal anaesthesia had already lowered considerably the post-operative mortality. The fall of blood pressure during anaesthesia, without marked increase of pulse rate, had seldom caused him anxiety. In a few instances under his own observation as large a drop in blood pressure as 60 per cent. had occurred, but the pulse rate was only slightly increased, and on the patient being returned to bed there was rapid recovery. Constant blood pressure readings should be made throughout serious operations under spinal anaesthesia, but the most important danger signal was the pulse. The position of operation was important. When the Trendelenburg position had been employed, return to the level should not take place for at least two or three hours. It was very important to keep the patient on an inclined plane, with the head low, this was the position in which he should be taken from the operating room, and the foot of the bed should be raised. Except in a few of his cases, any nausea or vomiting had been slight, and headache was extremely rare. This he attributed to his use of a small and sharp needle, reducing to the minimum the size of the hole in the theca. He had had two cases of external rectus paresis, one of which lasted for some weeks. There were also a few cases of transitory stiffness of the muscles of the neck. Abdominal distension had occasionally occurred, but this was by no means peculiar to operations under spinal anaesthesia. When undesirable after-effects followed operations under general anaesthesia, it was difficult to pin the anaesthetic down as the sole cause for the reason that there were several other possibilities which might be suggested, but with such complications as had been reported in connexion with spinal anaesthesia there were no loopholes. He could not explain how these rare sequelae occurred, nor how they might be avoided. Until failures as well as successes were reported it would not be known how spinal anaesthesia compared with other methods.

Mr J. P. LOCKHART-MUMFORD said that inhalation anaesthesia which caused vomiting and loss of appetite during the days immediately following operation was distinctly prejudicial to the work which the surgeon could do. It was no more than begin, and he was prepared even to run a rather greater risk with the anaesthetic if the method was free from these disadvantages. He thought that for operations up to the umbilicus there was no reason to prefer about regional anaesthesia, which was a difficult method, when spinal anaesthesia was available. In his opinion any really serious drawbacks attending the use of spinal anaesthesia had been due to faulty technique, such as the injection of an unsuitable substance or careless use of the needle. He had experienced only the trouble of the lowering of the blood pressure, to which everyone was accustomed, and in one case diplopia. In spinal anaesthesia

a patient was at the mercy of gravity. If, four or five minutes after the spinal anaesthetic was injected, the patient was slumped so that his head and chest were lower than any other part of his body no serious trouble was likely to ensue. The patient should always be moved on a trolley—the position could not be maintained properly on a stretcher. The keeping down of the head averted subsequent headache, at least to any more than a mild degree. The solution employed in his experience had been storaine Billou's, 10 per cent. He had never seen any case of idiosyncrasy to storaine.

Mr. CORDON TAYLOR said that he had used spinal anaesthesia first of all in cases where he expected shock. When amputations and severe operations were done on the lower limb spinal anaesthesia was extremely useful, as it also was in excision of the rectum and gynaecological operations. A second class of cases in which he had used it consisted of those in which the patient had some general constitutional disease rendering the administration of a general anaesthetic impossible or inadvisable. In a third class of cases he had used it for his own comfort, these were cases in which he felt the operation was going to be mechanically difficult, such as for carcinoma of the pelvic colon.

Dr. H. V. PACE said that he had always been in the habit of giving slight general anaesthesia before making the spinal injection, this was for the comfort of the patient, and he had not found the result affected. For the last four years he had been using a very fine needle—22 standard wire gauge, the usual needle of commerce being 16 standard—and in his last 100 cases with this small needle only one had headache had occurred. It was not only after the operation that the head should be lowered, but the patient should be sloped with the head lowest all the time from the injection onwards or at least from a very few minutes after the injection.

Dr. Z. MEXELL had heard of a good many complications following spinal anaesthesia, and severe headache was reputed to be a very common sequel. The neurologist, indeed, now recognized a definite disease known as storaine-rabies. Cases had come to the National Hospital—even cases of children where no question of ordinary rabies would arise—who showed complete loss of intelligence, small pupils etc., following on spinal anaesthesia. He did not know that the fall of blood pressure which was quite definite was a serious complication because it was quite easy to combat this and for some time he had been accustomed to give either a fairly big dose of camphor or some strychnine immediately after making the spinal puncture. His objection to spinal anaesthesia as a routine was the uncertainty of its action. He could not judge what dose it was necessary to give to any individual, the anaesthesia following a fairly uniform dose varied enormously with different persons, as did the length of time which it lasted. If a surgeon was relying on the anaesthetist to give a proper anaesthesia for longer than three-quarters of an hour or an hour a general anaesthetic became necessary. In America very little spinal anaesthesia was done there it was regional or splanchnic when an injection anaesthetic was given.

Dr. C. F. HADFIELD had given storaine Billou's solution for ten or twelve years, and had had none of the ill effects mentioned in the discussion. At his hospital (Prince of Wales, Tottenham), largely a local hospital to which the same patients returned time and again, although spinal anaesthesia had been regularly practised not a single case of so-called storaine-rabies had ever been seen. He had to confess however to a certain mortality with spinal anaesthesia and he was of opinion that the mortality with storaine was greater than with ether. One puzzling case which had shaken his faith in spinal anaesthesia was that of a woman otherwise healthy, operated on for fibroid. Under the anaesthetic she became blue and could not get respiration. Artificial respiration was tried and proved impossible, oxygen was introduced without result and the woman herself made efforts to get breath and could not and death ensued. He had discussed this case with Dr. H. H. Dale who pointed out a parallel condition in an animal given a fatal dose of histamine. On such an animal it was impossible to do artificial respiration, if oxygen were forced into the lung it would burst into the pleura but

it would not get into the alveoli. Apparently what happened was spasm of the small bronchioles. Dr. Hadfield personally did not like to combine a light general anaesthetic with the spinal analgesia. He thought better results were obtained with "trilight sleep." With regard to headaches, these seemed less likely to occur after a serious than after a minor operation, probably because, after a serious operation, the patient remained very still for a long time, whereas after a minor operation he moved about.

Mr. H. F. G. BOYLE believed that there was a bigger mortality with storaine spinal anaesthesia than with most other anaesthetics, and other members spoke of a possible toxic action of storaine. Mr. HOWARD JONES thought that if novocain were used instead of storaine fewer bad results would be reported. He had abandoned storaine some years ago on account of its relative toxicity. He also believed that the fall of blood pressure was less with novocain than with storaine. Mr. ASHLEY DALT thought that patients should be kept in bed for several days after spinal anaesthesia. Dr. P. J. CLARKE had seen two instances in which spinal anaesthesia was followed by paralysis of the rectum and incontinence. Both patients had a positive Wassermann reaction. Dr. JOSEPH BLOMFIELD said that the discussion had brought out the fact that there were two sides to the question, and it certainly could not be claimed that the method of spinal anaesthesia was the right one in all circumstances. He mentioned two cases reported in a French journal, of loss of control of the bladder lasting, for eighteen months and for three years respectively after spinal anaesthesia. Dr. CECIL HUGHES briefly replied to some of the detailed points raised.

## TROPICAL DISEASES AND PARASITOLOGY

The Section of Tropical Diseases and Parasitology of the Royal Society of Medicine held its first meeting of the new session on November 3rd with Major General D. HANLEY, a vice president, in the chair. A number of papers on tropical diseases and parasitology were read.

### *Blastomycosis Cutis*

Dr. ALDO CASTELLANI read a paper on "Blastomycosis cutis." Any pathological condition of the skin he said due to yeast-like fungi was usually called blastomycosis. The term "yeast-like" was a useful practical term referring to roundish or oval fungi with no mycelium. Two main types of the condition could be recognized—blastomycoid and cryptococoid. The former were larger cells with a well marked double contour due to the thick membrane. The internal granulations were larger than in the cryptococoid type in which they were sometimes absent. The lesions however, were similar, although the parasites were totally different in culture. There was no need, however, to adopt a fine botanical classification, and he usually separated them by observing the fungi in a hanging drop culture. If free budding cells were present the fungus belonged to the genera *Saccharomyces*, *Cryptococcus* etc., while if budding cells were absent it belonged to the genus *Blastomyces*. Clinically several types of blastomycosis existed. The commonest was blastomycosis verrucosa while other types were blastomycosis ulcerativa profunda (*Coccidioides* type), blastomycosis gumma, blastomycosis glanialis, and blastomycosis furunculosa. Blastomycosis verrucosa was characterized by raised patches with a verrucose or papillomatous surface resembling skin tuberculosis or warts. It had several subtypes. The commonest affected the skin only, and although cosmopolitan in its distribution it was commonest in the tropics and sub-tropics. The second type affected the oral and nasal mucosa as well as the skin, and was found mainly in South America. The third, affecting the tongue, had been reported from Ceylon and the last type affected the skin first or all, but later became systemic, with a general infection and pyrexia.

The speaker then described cases illustrating the various types. He said that blastomycosis ulcerativa profunda affected mainly the deeper organs, and rarely caused any skin lesion. It was due to a *Cryptococcus*. Blastomycosis

glutealis caused a diffuse induration of the skin in the gluteal region, and tended to become chronic. It possessed numerous sinuses discharging a thin pus, and was caused by a species of monilia or cryptococcus. Blastomycosis fungicola was very distinct clinically from the other types, and, indeed, it resembled ordinary boils to such an extent that it could only be distinguished from them with difficulty. It was often on the scalp, and the hair sometimes fell off, causing permanent baldness. In unopened sores the fungus was found in almost pure culture, but in open boils it was so heavily masked by a staphylococcus that diagnosis was difficult. It could be cured by doses of potassium iodide. There were other superficial conditions of the skin caused by yeast-like fungi, and called blastomycosis epidermides. These were of two types. The first showed no sign of inflammation, and consisted of brownish patches resembling dirt on the skin of the chest and limbs. Cryptococci were found on scraping the lesions. The second was mainly inguinal, where the skin was reddened and slightly inflamed. There were no raised edges to the patches, however, and there was only slight itching. It was often secondary to a fungus of the generic epidermophyton or trichophyton.

Dr. Castellani wished to emphasize three main points. Blastomycosis was not tropical, but cosmopolitan. It was first from 1910 in the southern United States, and it also occurred in Europe. Blastomycosis was not caused by a single species, genus, or even family of fungus.

Blastomycosis was best treated with massive doses of potassium iodide (one drachm three times daily), and if such quantities of the drug were badly tolerated large doses of sodium bicarbonate should be administered with them.

#### Malaria

Dr. BROUGHTON ALCOCK drew attention to the importance of house infection in the transmission of malaria, and showed a series of slides illustrating the difficulties which planters in Malaya had to face in attempting to eradicate mosquitoes. Malaria was still very common in some of the estates there. Mosquitoes indoors were more often infected than those out of doors, and he recommended house destruction of mosquitoes every eight to ten days by means of sulphur fumes or some similar measure. Houses should be planned in these areas on suitable lines, and trees should not be planted too near the houses, as they afforded protection for the insects.

Dr. SCOTT MACFIE communicated a paper on a species of malarial parasite from a baboon which resembles *Plasmodium vivax*, but only very slightly enlarges the red cells. The parasite appeared to be pathogenic for the monkey. Malaria in apes was of special importance to the medical man, and types identical with the human species had been identified in apes, although experimentally they had not been transferred to man.

Dr. J. GORDON THOMSON discussed the stippling of the red cells in malaria (Mayer's dots), and drew attention to the irregularity with which the typical picture could be obtained. It apparently depended on some staining reaction of which we were still ignorant.

Dr. CHRISTIE HENDERSON described a case of human retinomyiasis of the eye. The infection had been required through Stenson's duct. The case was cured by means of large doses of potassium iodide.

#### OBSTETRICS AND GYNAECOLOGY

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on October 21st, the president, Mr. COMYNS BERKELEY, in the chair, Mr. A. L. WALKER showed a specimen illustrating rupture of the uterus following Cæsarean section.

Mr. Walker said that the patient had had a Cæsarean section performed two years previously, followed by an aseptic puerperium. It had been originally intended that the labour should proceed naturally, but at its onset she was seized with violent abdominal pain, and developed signs of internal hæmorrhage. She was only admitted to hospital eight hours after the

appearance of the symptoms, and was then in so serious a condition that complete hysterectomy was performed at once. The Cæsarean section scar of the uterus was found to consist merely of fibrous tissue over a considerable extent, and rupture had occurred through part of this. An ovoid hole, almost the size of a hen's egg, was found on the maternal surface of the placenta, visible through the uterine perforation. The patient made an uninterupted recovery.

Mr. A. C. PALMER, in a brief communication on the incidence of carcinoma of the body of the uterus, mentioned the figures quoted by previous observers, and recounted a series of cases at King's College Hospital and the London Hospital. He concluded that the condition occurred at an earlier age than had been previously thought. He referred to one case of a sarcomatous polypus which had been discovered in a patient aged 19.

Sir EWEN MACLEAN then read a paper, illustrated by lantern slides, describing his visit to some of the medical schools of Canada and the United States of America. He made special reference to the teaching of obstetrics and gynaecology, and to the training of midwives.

#### ACUTE EAR CONDITIONS

At a meeting of the Brighton and Sussex Medical Surgical Society on November 3rd, the President, Dr. DONALD HALL, in the chair, Dr. A. CROW read a paper on "The acute ear."

Dr. Crow deplored the attitude of textbook writers who treated of deafness, otorrhoea, tinnitus, meningitis, and the dismal end-results of the acute ear as though they were casual occurrences, the appearance of such preventable symptoms called not for complacency, but for scandalized comment. The signs and symptoms of an acute ear were deduced from a consideration of the essential anatomy and pathology, they were temperature, pain, bulging drum, primary mastoid tenderness from congestion of the mastoid emissary vein, slight deafness, and perhaps vertigo. By means of blackboard drawings, the various appearances of the normal and abnormal drum were indicated, and the differential diagnosis was discussed. Emphasis was laid on the need for early paracentesis once tension in the middle ear had been diagnosed, for one was not primarily dealing with an abscess, but with a threat to ultimate function by reason of tension in the most delicate piece of mechanism in the body. Hence there could be no delay, as in the case of abscesses elsewhere, for the wall of resistance to be built up, such a process fixed the stapes, caused sloughing of the membrane, immobilized the ossicular chain, and drove infection into the bone, establishing a chronic otorrhoea. Dr. Crow maintained that paracentesis was an operation of general practice, and he described the procedure in detail. Dealing with the question of mastoiditis, it was shown that here, on the other hand, no special function preservation was involved, but life itself was threatened by the proximity of a potential abscess to vital structures, although it might be argued that the preservation of hearing and the preservation of life were of approximately equal importance. Charts of the prognosis of the acute ear were demonstrated, and an attempt was made to show that after the subsidence of the acute otitis element any return of either pain, temperature, or tenderness was a diagnostic of mastoid pus, yet secondary mastoid tenderness was not a sign to wait for, the dangerous cases, with deep-seated pus, presented no such sign. Dr. Crow held that a needless amount of mystery was associated with middle-ear diagnosis. If a patient was seen twice daily, and the pain and temperature carefully charted, and if it was remembered that the essence of diagnosis was appreciation of the sequence of symptoms, the situation being clarified by free middle-ear drainage, then he could see no difficulty about establishing a diagnosis, at any rate in patients above the age of 3. A new sense of responsibility in regard to the hearing function was needed. Deafness being a disability more dreadful than blindness, and only a little less terrible than insanity, pity for its victims had no sincerity if it did not translate itself into a resolve to protect them from a similar fate.

## THE LIVER TREATMENT OF PERNICIOUS ANAEMIA

At a meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland on October 28th, the president Dr G E NESBITT in the chair, Dr H I MOORE read a joint paper by himself and Dr A R J DUNGAN on the Minot-Murphy diet in the treatment of pernicious anaemia.

Dr Moore discussed the principles of this liver diet in the treatment of the disease and reviewed the literature. The details of five patients treated in this way and observed for from seven to twelve months were given. In all the cases clinical improvement started within a few days of beginning treatment there was a marked and rapid increase in the number of red blood corpuscles and the haemoglobin the leucocytes tended to increase in number and the colour index diminished in four cases, and anisocytosis and poikilocytosis disappeared. In fact, complete remissions with practically normal blood counts were induced in all the patients and the remissions had persisted to the present. The tongue signs also cleared up and the patients were able to resume their normal modes of life. It was concluded that the Minot-Murphy diet treatment of pernicious anaemia was astonishingly successful in inducing a remission.

Dr A R J DUNGAN explained that by reason of the conditions under which the work was carried on a more detailed laboratory study of the cases was not possible. The colour indices had been calculated on the classical basis but owing to the marked sex and age variations in both red cell count and haemoglobin content he doubted whether this procedure was altogether advisable. The success of the liver diet might possibly be a point against the theory that chronic intoxication was the cause of pernicious anaemia since it seemed unlikely that bone marrow undergoing continuous slow poisoning would recover function so dramatically after the administration of a comparatively simple chemical substance. On the other hand, the anaemia might be the result of damage caused by a previous infection such as was believed to occur in the pancreas in diabetes. In some of the cases of Minot and Murphy the actual red corpuscle volume had increased more than fourfold under treatment and had blood volume studies been possible in the present series they would presumably have shown a similar result.

Dr L ABRAMSON said that he had treated three patients by this method. The first, a case of pernicious anaemia was so ill on admission to hospital that he could not tolerate liver or any solid food and the treatment had not had a fair trial. The second, a typical case of pernicious anaemia was admitted to hospital with a red cell count of 1,310,000 per cmm and a haemoglobin percentage of 35. After nineteen days of liver feeding the red cell count had increased to close on 4 millions per cmm, and the haemoglobin to 60 per cent. Improvement in reticulocytes described by Minot and Murphy was not noted in this case. The third patient treated had severe secondary anaemia and showed no improvement on liver treatment. Dr Abramson remarked that it would be necessary to wait for some years before the results of this treatment could be determined. It was encouraging to read that patients had been followed for over three years, without relapse occurring. The liver treatment was an important departure in therapeutics generally, and in regard to pernicious anaemia it was not only a promising therapeutic method but was likely to clear up the etiology of this hitherto obscure complaint. He thought that the success of liver feeding controverted the theory of intestinal toxemia.

Dr V M STACEY reported the case of a woman, aged 25, who for three months prior to admission to hospital had had pernicious anaemia symptoms and a typical blood picture. She had been unable to take arsenic by the mouth but had had arsenic injections. One week after liver treatment had been started there was very marked improvement and she left hospital eventually healthy and fit, though a little

anaemic. She was now in excellent health, and was taking liver and hydrochloric acid daily. In the diagnosis of doubtful cases of pernicious anaemia he thought the most reliable test was the estimation of bilirubin in the blood. Since he had started this he had never found a case of pernicious anaemia in which it had not held good.

Professor PARSONS said that perhaps the new knowledge of the value of liver feeding in pernicious anaemia would later on throw light on the functions of the spleen in relation to blood formation.

Professor BIGGER asked how much of the liver extract referred to by Dr Moore was obtained from a given weight of liver substance. He also asked if liver treatment had been tried in such forms of secondary anaemia as bothriophthalmus anaemia.

Professor J M O'CONNOR said that he could hardly regard liver treatment as being successful owing to its action on the bone marrow. If the results were due to bone marrow stimulation a distinct change in the white blood corpuscle count would be expected, the polymuclear cells increasing out of proportion to the lymphocytes.

Dr A R PARSONS thought that the real difficulty was to treat pernicious anaemia in the relapse. No one could yet say that the results of liver treatment were going to be permanent, but it was encouraging to note that Minot, even in cases of a third attack, had got nearly as good results from it as he had in first attacks.

Dr R A Q O'MEARA stated that the microscopical picture of the bone marrow in pernicious anaemia was not one of destruction, but of very active regeneration. A toxic origin of the disease was suggested by the peculiar cases in which pernicious anaemia started with achlorhydria, followed by subacute combined degeneration, and later by symptoms of anaemia. He agreed with Dr Stacey that the van den Bergh reaction gave valuable information as to the nature of the anaemia, and he thought it would be interesting to see the effect of liver treatment on the bilirubin content of the blood.

Dr H QUILLAN mentioned the case of a patient of his who was not able to take liver at first, but was now able to take a certain amount. In cases like this a liver extract or powder would be a great improvement. He had treated two other patients, one had greatly improved, but the other had remained very much the same since the start of the treatment.

Dr E T FREEMAN asked if any alteration at all had been noticed in the blood pressure of patients who had taken large quantities of liver.

Dr MOORE in his reply, said that he believed a blood pressure lowering fraction had been isolated from the liver. He thought that care should be taken for the present about mentioning the word "gland" until it was found out whether the substance mentioned was a hormone or not. It had been stated that the liver was much more effective given raw than if given cooked. In some cases he had found that the blood pressure had risen, but only to a slight extent, and not more than would be accounted for by the patient's general improvement.

At a meeting of the Newcastle and Northern Counties Medical Society in the Royal Victoria Infirmary, Newcastle, on November 3rd, Dr STANLEY RAW in the chair, Dr J C SPENCE read a paper entitled "The liver and pernicious anaemia, in which he reported the results of cases treated in the Infirmary by the liver diet of Minot and Murphy.

Dr Spence first paid tribute to the manner in which these American workers had approached and pursued their researches, furnishing a good example of the application of the scientific method to clinical problems, the result would rank as one of the most important discoveries in medicine in recent years. Their discovery had a greater significance than the mere provision of a cure for pernicious anaemia for it would probably throw fresh light on physiological processes in the liver and in the generation of blood cells. Dr Spence described the results of empiry-

ing a liver diet, or an effective liver extract, in twenty successive cases of pernicious anaemia which had been treated in the Newcastle Infirmary since the beginning of the year, and contrasted these with ten control cases in which older methods of treatment had been used. These results confirmed those of Minot and Murphy. In nineteen cases there had been a prompt and rapid rise of red blood cells, with quick improvement of the patient's general condition. One patient alone failed to respond, for some reason which was not yet clear. In the nineteen successful cases the red cells had risen to more than 4½ million within two months, and in some cases had reached 6 million. The tendency to relapse when the adequate amount of liver in the diet was not taken continuously was mentioned. Dr Spence drew attention to the fact that the response to this diet appeared to be quantitative, depending on the amount taken, and that harm might result from taking too much liver after the stage of cure had been reached. This was illustrated by three patients who had eaten a pound of liver daily for three months after the blood cells had been restored to their normal level. In each of them the red cells reached 6 million, two of the patients suffered from acute gout, and the third developed the more serious complication of venous thrombosis with oedema of the legs. This suggested that it was necessary to control the dosage of the liver by frequent blood counts, in practice it was found that when a cure had been established it was sufficient in most cases to maintain the patient's condition by giving about eight ounces of liver three times a week. The danger of provoking gout would probably be overcome when treatment by liver feeding was replaced by the giving of an effective liver extract. Following the lines laid down by Cohn, an extract had been prepared in the chemical pathology department of the Infirmary which had been used with success in three cases, the patients were given daily 20 to 25 grams of this extract, a reticulocyte crisis had been produced, and a rise of red cells with improvement of the symptoms followed within seven days. The sudden appearance of reticulated red cells in the blood stream was one of the most interesting and important signs of the restoration of the bone marrow to its normal state of function. A clinical sign, which was almost equally dramatic, was the rapid abolition of the tongue symptoms. These had disappeared in one severe case before any rise in blood cells had taken place, and before the height of the "reticulocyte crisis" had been reached, they might be the first sign of improvement. Dr Spence discussed the bearing of Minot and Murphy's work on the pathogenesis of pernicious anaemia. It appeared to dispose of the prevalent theory that a haemolytic process was concerned. Haemolytic streptococci in the gut had probably nothing to do with the disease.

## JAMES MACKENZIE INSTITUTE

### Superficial Abdominal Pain

At the James Mackenzie Institute for Clinical Research, St Andrews, on October 18th, Professor JOHN FRASER (Edinburgh) read a paper on superficial pain as an aid in the differential diagnosis of abdominal conditions. He believed that superficial pain in one or more of its various manifestations might offer enormous assistance in the elucidation of an otherwise obscure problem, and paid a tribute to the lasting value of the work of Sir James Mackenzie on this question. Professor Fraser dealt particularly with the manifestations of superficial pain—hyperaesthesia, and referred pain. In each instance he interpreted the phenomenon in terms of the anatomy and physiology, and the signs and concluded by an attempt to assess their value. Hyperaesthesia and hyperalgesia in spinal areas, the irritating upon an irritability of certain of the deranged viscera having arisen as the result of afferent impulse from the reception of a second somatic stimulus transmitted from the surfaces corresponding to the one so as to be represented was apt to be magnified or altered.

to the sensorium as a hyperalgesia or a hyperaesthesia. Professor Fraser found the most striking manifestations of the sign in connexion with appendicitis and infection of the gall bladder. In appendicitis it was positive in 58 per cent of cases. When present the distribution was remarkably constant along the area described as Sherris triangle, the distribution of the tenth and eleventh dorsal nerves. A great variety of factors might explain the incidence of the sign, and evidence was adduced to show that the responsible stimulus arose early in the pathological sequence, and that it might be due to the stretching of the mucous surface of the organ affected. For example, some of the most distinctive records arose in connexion with threadworms and concretions in the appendix. When the gall bladder was concerned the sign was more likely to be associated with small mobile stones than with a single large fixed stone. A variety of different diseases were considered in respect of the sign and the results of clinical referred pain was dealt with on a similar plan. The commonly accepted explanation of the sign was the projection to the surface by a disturbed sensorium of stimuli originally recorded as afferent impulses from a distant viscus. It was recorded that the evidence of the sign was more constant than that of hyperalgesia and hyperaesthesia, but great significance was attached to the difficulty of distinguishing true referred pain. This question was discussed in relation to the various manifestations of pain in appendicitis, and the significance in this connexion of epigastric pain. Various lesions were dealt with in detail, and an interesting record was noted in respect of the reference of pain in relation to gall bladder and common duct affections. The paper concluded with a short reference to the problem of local tenderness and the interpretation of muscular rigidity as a manifestation of underlying visceral disease.

### Symptomatology in Dyspepsia

On October 25th Dr R. O. ADAMSON (Glasgow) read a paper on some aspects of symptomatology in dyspepsia as met with in general practice. He referred first to the important place of the stomach in the alimentary tract and its governance by the autonomic nervous system in order to explain the wide appeal of disturbed gastric function. The subjective symptoms and the objective signs of dyspepsia were detailed, and all cases of dyspepsia and its symptoms were allocated to a place in a classification including disorders of the alimentary tract, whether of the stomach or some extra-gastric part of the tract, and disorders of the body outside the alimentary tract but still disturbing the gastric function. Some anatomical, physiological, and chemical details were considered in the light of their bearing on symptoms and function, on various types of dyspepsia, and on the relation of the stomach and symptoms to adjacent organs, such as the gall bladder and pancreas. The importance of the psychic factor in many cases of dyspepsia in practice was alluded to, also of the influence of that factor on gastric secretion and motility, with reference to the various limitations of gastric analysis. Focal symptoms were considered in more detail, especially the significance of discomfort and pain in relation to ingestion and various disorders and diseases of the stomach. Reflex symptoms, masquerading as gastric dyspepsia, were referred to, also the simulation of dyspepsia in the early symptoms of disease in organs remote from the alimentary tract. Dr Adamson next cited cases exemplifying some focal symptoms of nausea and vomiting, acid eructations and flatulence, considered flatulence in relation to aerophagy and other disturbances. Remote symptoms he dealt with as a whole and as an expression of autonomic nervous disturbance or toxemia, and he stressed the need for exhaustive inquiry into cases with various groups of symptoms. In conclusion, he discussed the manner of dyspepsia at different ages, and dealt on the necessity for the general practitioner to be familiar with the life-line of the patient, so as to regard dyspepsia as a thing in itself, but as a manifestation of disturbance of a complex organization.

## Rebelsus.

### CIVILIZING THE UNCIVILIZED

Mr. Pitt-Rivers's book on *The Clash of Culture and the Contact of Races* deals with some of the urgent problems which face the administrators of our dependencies in the government of native races, for whose welfare we are responsible in various parts of the world. He has studied at first hand the primitive communities in New Guinea, in the island's north of New Guinea and in the Society Islands, in order to find out why these communities exhibit a tendency to depopulation and extinction. It was to be supposed that by conferring the blessings of Western civilization on these peoples, their social elevation would be a conspicuous result, this, however, has by no means been the case. Certain races, it is true, have assimilated Western ideas with such advantage to themselves that their benefactors are not without apprehension as to the ultimate result, this is so with the negro population of the United States. But as a rule contact with Western civilization has been followed by race degeneration. Thus in the islands of Melanesia and Polynesia and other parts of the Pacific a great number of the populations are, as the author shows, declining and in many cases have declined to the point of extinction. This fact has been a frequent subject of official and unofficial inquiries during the past fifty years. In Tasmania the problem has ceased to exist, and is of small importance in Australia, for the simple reason that the Tasmanians have already died out and the aboriginal Australians are rapidly following the road to extinction. In the sweltering and fever-stricken islands of Melanesia and Polynesia, where native labour is indispensable, we are apparently fast exterminating the races which it is our best interest to preserve.

Many reasons have been given in explanation of the decadence of these populations, some refer to the effects of European interference—namely, change of habitat, the concentration of dwellings, European clothing, European food, the recruiting system and the segregation of the sexes on plantations, the abolition of the communal system and the authority of the chiefs, alcohol introduced diseases, obstacles to marriage, the abolition of native warfare and head hunting, the increase of infant mortality under the new conditions, and the abolition of polygamy. Others on the other hand, hold that the decadence is inherent in the native life and manners, Sir Hubert Murray, for example, has expressed the opinion with regard to certain Papuan tribes that 'it is difficult to imagine that people with such habits as they exhibit should ever increase, the only cause for surprise is that they should ever have come into existence at all.'

Mr. Pitt-Rivers has submitted these reasons to searching criticism and has come to the conclusion that decadence is due less to any specific cause such as alcohol, than to the disruption of the native civilization that has followed the introduction of Western ideas. With their cherished traditions and ideals, such as they are, shattered, it is no matter for wonder that they are unable forthwith to bridge the gulf which separates them from our modern civilization, which even to ourselves has its unattractive features in its wars and revolutions, its strikes and the drab conditions of the industrial regime, the natives must experience the discomforts of an entire misfit. By the destruction of their interest in life they become maladapted, a circumstance which throughout organic life is found to lead eventually to extinction. This fact was recognized by Stevenson, who was acquainted with conditions in the Pacific, he noticed that "where there have been fewest changes, important or unimportant, salutary or hurtful, there the race survives. Where there have been most, important or unimportant, salutary or hurtful, there it perishes." It is true that some races may perhaps possess no potential adaptability and in such cases it is not difficult to see what the effect of a disruption of the native civilization must be with the authority of their traditions gone, the purely animal

instincts would have the ascendancy. But even where a race has a high degree of potential civilization the tendency would be in the same direction if the disruption of the old tradition were not accompanied *passu* with an assimilation of the new. A middle course would seem to be the right way—retention and transformation of the old rather than its abolition. Some of our more enthusiastic pioneers in their civilizing propaganda among the natives would do well to take to heart the following advice of Gregory the Great, who, writing (D 601) to the Abbot Mellitus, said:

When therefore Almighty God shall bring you to the most reverend Bishop Augustine our brother tell him what I have upon mature deliberation on the affair of the English decreed upon viz that because they have been used to slaughter many oxen in the sacrifices to devils, some solemnity must be exchanged for them on that account as that on the day of the dedication, or of the nuptials of the holy martyrs they may build themselves butts and celebrate the solemnity with religious feasting and no more offer beasts to the devil but kill cattle to the praise of God in their eating. For there is no doubt that it is impossible to efface everything at once from their obdurate minds because he who endeavours to ascend to the highest places by degrees or steps and not by leaps.

Gregory's wisdom was justified in the result.

### DIAGNOSIS BY SIMPLE CLINICAL EXAMINATION

Felix LEJARS's book on clinical examination and diagnosis was first published in 1923, but although the edition was exhausted within a few months four years have been allowed to elapse before the issue of a second. The author has re-examined the whole work in order to make good any discoverable omissions, and has added 187 new figures. The new volume contains over 900 pages (not too many for the matter in hand) and 1,094 illustrations, most of them photographs from life, and may unhesitatingly be pronounced one of the best books of its kind in existence. It was written expressly for practitioners, this does not mean that it is not equally useful for students, but merely that the author visualizes not only abstract clinical facts and deductions, but has in mind also the practitioner at work and the patient under examination. All through the impression is received that Lejars in practice is himself being depicted, and that the book is in fact, a summary of his own long experience. In dealing with the subject he holds that, in the presence of a regional affection, two main questions arise. What should be thought of? and How is the region to be explored? These two questions mark out the ground plan of the book, a region is named, the lesion which should be thought of first is mentioned, and the steps of the exploration required to establish a diagnosis are then described, on the supposition that this lesion is eliminated from the diagnosis a second lesion is named, and the appropriate exploration described, and on so with all the other lesions that may affect the region. Great stress is laid on clinical exploration by eye and hand, which the author states, should precede all others. At the present day numerous special methods have been introduced—physical, chemical, and bacterial—but although they are important they have in no degree diminished the value and the necessity of learning the traditional method, and the latter should in every case be resorted to in the first instance. It is still essential for the practitioner to have an expert knowledge of and skill in conducting exploration by sight, palpation, and percussion, and if this traditional method is conducted in orderly fashion and according to its own proper technique it yields invaluable information. It is to this traditional exploration that the author devotes his book illustrating it with an abundance of figures which show the technique in actual application on patients suffering from the diseases under discussion. The latter fact renders the descriptions particularly vivid and confers on them in some measure the character of actual clinical demonstrations.

There is however, no attempt to belittle x rays and other modern methods of exploration, and where these are of primary importance as in supracondylar fractures of the femur, the fact is clearly stated, but the main object

*The Clash of Culture and the Contact of Races* By George Henry Lane-Fox Pitt Rivers. B.Sc. Oxon. London: G. Routledge and Son. Ltd. 1927. (Med. Sc. pp. xiv + 412. 1 plate. 18s. net.)

*Exploration Clinique et Diagnostique Clinique* Par Felix Lejars. Neuvième édition entièrement refondue. Paris: Masson et Cie. 1927. (Poés. 8vo pp. xii + 911. 164 figures. 160 fr. sans majoration.)

of the book appears to be to inculcate the necessity of possessing an expert equipment in the time-honoured methods of examination, and these are expounded in a masterly manner which renders the work one of high value.

### DISEASES OF THE HAEMOPOIETIC SYSTEM

THE ninth instalment of the *Nouveau Traité de Médecine*,\* edited by G. H. ROGER, F. VIDAL, and P. J. TEISSIER, is devoted to diseases of the blood and haemopoietic organs, and is written by nine contributors and admirably illustrated. M. Charles Aubertin, who supplies some of the most important articles, begins the volume with an account of the anaemias, in the article on chlorosis, written in collaboration with M. Mouquin, attention is drawn to the widespread declension of this once common malady, but the suggestion is thrown out that this may be in part due to more systematic blood examinations and a correspondingly more accurate diagnosis of secondary anaemias. A special chapter is devoted to the chloro-anaemia (oligosideremia) of young infants, which is identical with ordinary chlorosis and also is cured by iron. Pernicious anaemia is regarded as not absolutely commoner, but only more often diagnosed than in the past, and under this heading are included two special forms described in America—sickle-celled and phagocytic anaemias. After a separate description of aplastic anaemia there follows a full account of the grave symptomatic anaemias, the technique of transfusion being illustrated by a number of figures. Other forms of treatment of the grave anaemias are, of course, mentioned, but presumably the volume was in print before the effect of feeding with liver in pernicious anaemia became well known. The study of diseases connected with changes in the red blood corpuscles is completed by MM. Aubertin and Mouquin's article on polycythaemia and Vaquez's disease or erythraemia.

The blood conditions characterized by changes in the white cells and most of the diseases of the lymphatic glands occupy 240 pages, and are well described by M. A. Clerc. Under the heading of lymphadenie or lymphadenomatose there are included a number of conditions, such as Hodgkin's disease (entitled lymphogranulomatose maligne), mycosis fungoides, lymphosarcomatosis, and a number of glandular enlargements of undetermined origin without leukæmic bleed. M. Emile Weil divides haemophilia into the familial and the acquired forms, and in discussing the differential diagnosis refers to Osler's disease, meaning thereby not erythraemia (Vaquez-Osler's disease), but hereditary telangiectases, and thus supplies an eponym to be welcomed and adopted. The same authority writes on the pathology of the bone marrow and of the lymphatic glands, and, together with MM. Le Sourd and Pagniez, on purpura.

The last, and perhaps the best, section of this fine book of reference is on the diseases of the spleen, by MM. C. Aubertin and Leon Kindberg. Among the primary tumours of the organ splenoma, a term not familiar to British ears, is described as the commonest, and composed of giant and multinuclear cells derived from the macrophages of the spleen. There are good accounts of chronic splenic anaemia, which is rightly distinguished from Banti's disease or the complication of hepatic cirrhosis and of Gaucher's splenomegaly. Altogether this volume well maintains the reputation of this well known system of medicine.

### WORD-BLINDNESS AND MIRROR-WRITING

THE special disability in reading shown by some children and known as "word-blindness," and the phenomenon of "mirror-writing" shown by other children, are well known and interesting oddities. More attention has probably been given to the cases of word-blindness owing to the interest they afford to the ophthalmic surgeon, who generally discovers them, for at the outset the difficulty of the child is commonly thought to be due to inability to see. Further, the condition of these cases was so admirably worked out by the late Dr J. Hinselwood of Glasgow in his several papers and his book on the subject. Up till

now the two conditions of word-blindness and mirror-writing have not been thought to be related. Now the psychologists have taken a hand in investigating them, and they suggest that there is a connexion. A monograph has been issued in the series Harvard Monographs in Education, entitled *Special Disabilities in Learning to Read and Write*. There is a most detailed investigation of a case of word-blindness by Miss E. E. Lord, some account of mirror-writing by Mr L. Carmichael, and the two pieces of work are correlated by Dr Walter F. Dearborn.

The two conditions are held to have certain features in common, a consideration of which may be reciprocally illuminating for the understanding of each condition. Word-blindness has until recent years remained the concern chiefly of the neurologist and ophthalmologist, and has usually been regarded by them as either a congenital defect or an acquired and pathological condition due to some lesion in certain areas of the brain. Mirror-writing has, on the other hand, usually been looked upon as one of the possible consequences of a mere biological variation—namely, of extreme left-handedness. Although it has been more commonly observed in the subnormal, it has not itself been regarded as congenital (although left-handedness has been so considered) or distinctly pathological. The educational psychologists who have more recently interested themselves in these conditions have come to hold much the same point of view in regard to extreme reading disability or word-blindness as has been generally held in regard to mirror-writing. They have argued that disability or inability in reading forms simply "the far end of the normal distribution" of the abilities in question, have questioned the existence of congenital factors, and have considered "the possibility that inhibiting habits, however acquired, may be at the bottom of the inability." Cyril Burt has described such a situation. "Backwardness specifically in reading is often due to illness or absence between the ages of 6 and 8. It is during this period that the ordinary child is taught to read. If he fails to learn to do so then, he is still, on the grounds of age, transferred at the usual time from the infants' department. Once in the senior school he meets with nobody who feels it his business, or perhaps with nobody who feels himself able, to teach a child the rudiments of reading, and so he lingers on, and a few years later appears, in a very literal sense, word-blind." Usually, however, specific intellectual shortcomings may be discovered which, even under changed conditions and the most capable instruction, limit the individual's learning.

To connect word blindness and mirror-writing seems at first glance to be a wide stretch. But there are interesting cases. There is the "tail-endor" reader, the left-handed subject who appears to be also left-eyed, as it were, who tries to read from the right instead of from the left, and who reads "saw" as "was." There are also reported a greater incidence of speech defects amongst the left-handed, which points to further complication in their learning to read.

The subject is dealt with in a most interesting fashion in the paper included in this monograph from Harvard.

### A CRITIC OF HOSPITAL GOVERNANCE

Dr M. B. SHIPSEY of Birmingham is possessed of an intense antagonism to present methods of hospital management, and he has delivered his soul in a pamphlet which is entitled *The Present System in Hospitals Generally, with Special Reference to the Hospitals of Birmingham, and a Review of the Medical Profession Pertaining to Hospitals and Other Sidelights*. The title is lengthy, and would cover a vast deal of matter. But from his pages it would appear that his real aim is an attack upon hospital governance by laymen. "Hospital committees," they seem to be retired business gentlemen pumped up by their

own exalted opinions of themselves puffing, pompous, exalted, transcendent, almighty hospital governors, so much do they take it upon themselves to ponderously overshadow the real work done in hospitals by one body alone, viz, doctors, whilst not forgetting those who assist the medical profession, i.e., nurses." He is equally caustic in his comments upon the guardians of the poor who administer the great infirmaries. The author has a free flow of words and a rich vocabulary of descriptive adjectives, but we think he has so far overdone his argument as to cause a smile where he would desire to invoke agreement. His objection of ecclesiastical intrigue amounts almost to the level of the spy mania shown in certain quarters in the near past. He writes of the hospitals of Birmingham, and we have some knowledge of the members of hospital boards of that city, and know them to be sane, sensible men and women who give lavishly of their time and substance to the hospitals. The writer of this note has served upon no fewer than six voluntary hospitals in London and the country, and in some in such a capacity as brought him into intimate relations with his board. During a period of thirty years he has found nothing of the monstrous domination alleged by Dr Shipsey, who argues that the management of the hospitals should be in the hands of the doctors. Most hospitals have medical committees, and through these the staff exert an effective influence. It might be a questionable advantage for the staff to have to deal with "serving of tables," if they did, how would their proper work fare? We commend to Dr Shipsey the study of the quaint old story of Jotham. The trees went forth to appoint a king over them and they said unto the olive tree, Reign thou over us. But the olive tree said unto them, Should I leave my fatness wherewith by me thou honour God and man, and go to be promoted over the trees? And for like reasons the vine and fig tree refused the high office, only the bramble was willing to take on the job.

### SKIN DISEASES

The third edition of Dr ORMSBY'S well known textbook on *Diseases of the Skin*\* reminds us again that the growth of textbooks resembles in many ways the growth of certain classes of insects, not only is there a general increase of dimensions but besides, an incomplete metamorphosis is brought about by the suppression of some features and the development of others as successive editions make their appearance. Textbooks, however, unlike insects, never reach finality—the latest edition is never the perfect in age. If perfection be unattainable Dr Ormsby has at least produced a work which is as complete as it is possible to make it, and as up to date as a determined pursuit of the latest dermatological publications can achieve. Our only criticism of the exhaustive references he has provided is that he might perhaps have been a little more discriminating in his choice of observers to quote. One omission is rather surprising, there is no mention of the recent work on treatment of ringworm of the scalp by thallium acetate. This work we owe chiefly to Buschke, and it is a step of great importance. Otherwise we have nothing but praise for Dr Ormsby's magnum opus, which should be in the hands of all interested in dermatology. It is clearly written and well illustrated. There are only three coloured plates but there are many well reproduced photographs which bring out excellently the points to be emphasised.

The *Outlines of Common Skin Diseases*, by Dr T. C. CURRIER of Baltimore, is intended to form an extremely short cut to arguino is of the cutaneous disorders more frequently met with, and we can easily imagine that it will prove useful to practitioners whose knowledge of dermatology is not profound and who are so placed that they find it difficult to obtain help in the problems of practice. The section on the regional distribution of the common disease, should be particularly helpful. One item

in that list, however, we must take exception to—that is, the mention of psoriasis as first among such lesions found on the face. Although it is true that in severe cases psoriasis may occur there, this is so rare that its presence is noteworthy, and it is never seen on the face in the absence of lesions on other parts. Other sections include hints on diet and cancer, a few notes on treatment and some dermatological aphorisms. There are a number of illustrations, which, although extremely small are clear. The author is careful to point out that he does not intend this pamphlet to take the place of a textbook, it certainly could not.

### NOTES ON BOOKS

No profession, we imagine is recruited more largely than medicine from the Rugby football field and the game certainly owes much to the generations of medical students who have thrown themselves into it for the glory of their schools. Guy's is indeed the oldest club now playing and the Rugby Cup Tie is still the great sporting event of the hospital year. There are still among us veterans of early international matches in the seventies—J. A. Macdonald, E. B. Turner, and his brother C. R.—and leading figures of later decades such as Andrew Balfour, J. R. C. Crebber, C. T. Scott, E. T. Morgan and Louis Craig while in recent years L. G. Brown, W. D. Doherty, R. Cove Smith and D. J. MacMunn have helped to build up the forward game of today. These names and many others are honoured throughout the medical schools of England, Scotland, Ireland and Wales and their mere recital should be excuse enough for mentioning the appearance of a new book, *Pugger*\*, by W. W. Wakefield (the English captain) and H. P. Marshall, which every lover of the game will want to read. The first part consists of Wakefield's own reminiscences, the second is a full length treatise on the theory and practice of modern Rugby football and the third is a compendium of club histories and international records etc. for statistically minded devotees. The whole thing is very well done and elaborately illustrated, and those who disagree with one of the authors' many precepts will like it none the worse for that. Every page breathes the true spirit of the game.

As part of the campaign it is carrying out to educate the public in the need for proper care of their teeth the Dental Board of the United Kingdom has lately issued a small book entitled *Hygiene of the Mouth and Teeth*†. This has been prepared primarily for the use of teachers and the Board proposes to make a wide distribution of copies to public elementary and secondary schools in the British Isles. The contents are written in simple language logically arranged and well illustrated. An informal introduction is contributed by Sir Francis Duke, a former chairman of the Dental Board, in which he acknowledges the help given in the compilation of the volume by Dr H. C. T. Langdon, medical officer of the Board of Education and a member of the Executive Committee of the Board's Dental Health Education Committee.

### PREPARATIONS AND APPLIANCES

#### MODIFICATION OF THE THOMSON-WALKER PEPPACOR

Mr JOHN S. LEVY, U.C. assistant surgeon, Royal United Hospital Bath, has devised a new blade for use with the Thomson-Walker pattern of bladder retractor. It is made of soft metal, which can be moulded to fit the vesical wall and prevent it from puckering in front of the prostatic pouch. The instrument is made by Messrs Maw and Sons Ltd., 7, Aldersgate Street, E.C.1.

#### AN IMPROVED RING PEPPACOR

Messrs Allen and Hanbury Ltd., 48, Wigmore Street, London, have manufactured a new form of combination ring pessary. It is fitted with springs, like the ordinary watch ring pessary and is padded with moulded sponge rubber with an outer covering of smooth sheet rubber. The advantages claimed for the Wigmore Spongy Ring Pessary are that it is more comfortable than the unpadded watch ring pattern and more resistant than the un-reinforced sponge rubber appliance.

\* *Outline of Common Skin Diseases*, by T. Caspar Culver, M.D. London: Baillière Tindall and Cox, 1927. (4 x 8 pp. 5s. 6d. figures, net.)

## WOOLWICH WAR MEMORIAL HOSPITAL

OPENING BY THE DUKE OF YORK

H R H THE DUKE OF YORK, accompanied by the Duchess, visited Woolwich on November 2nd to open the general hospital which that borough has erected in memory of its more than six thousand citizens who lost their lives in the great war. The building stands in thirteen acres of ground on the highest point of Shooter's Hill, more than 400 feet above sea-level. It is newly opposite the famous Bull Inn, where Dick Turpin is reputed to have put the landlady on the fire, and hereabouts must be the spot where Don Juan mused on the morality or otherwise of the great city which he saw below him to the north and west.

The hospital is being built in three sections, of which only the first has been completed. This section accommodates 110 beds, including a maternity ward with six beds and two isolation beds, together with a sunlight and electro-therapeutic department. The second section will comprise, in addition to two more ward blocks, a paying patients' pavilion, a nurses' home, a laundry, and a pathological department, and the third section two more ward blocks, bringing up the total number of beds to 344. The administration block for the whole hospital, with a noble architectural frontage, has also been completed.

The greater part of the population of Woolwich appeared to participate in the opening proceedings. Probably never before has a hospital been opened within the sight and hearing of so vast a multitude. The ceremony took place in the open air on a very high dais, and the usual devices of microphone and loud speakers made the speeches audible at a great distance. Opportunity was taken for some military display, and a guard of honour from the Royal Artillery Depot was mounted in front of the hospital, with which was a contingent of men and women representing the British Legion, the Old Contemptibles' Association, and the British Red Cross and the Order of St John of Jerusalem. Their Royal Highnesses were received by the Mayor of Woolwich (Councillor Brieffoot), the chairman of the Hospital Fund (Mr E H Kemp), the secretary superintendent (Mr Edwin Radford, J P), and others, and among those presented were Lord Dawson of Penn, who is consulting physician to the new hospital, Sir Berkeley Moynihan, Bt, who is consulting surgeon, Mr Cecil Rowntree, honorary surgeon and chairman of the medical committee, Dr C F T East, honorary physician, and Dr W Cowie, representing the medical practitioners of the district.

The first act of the royal visitors was to unveil a Book of Remembrance in which the more than six thousand names of the fallen are inscribed. One page of this volume is to be turned every day, following a custom practised at Canterbury Cathedral and perhaps elsewhere, and the book has been placed in a specially built hall, panelled with coloured marbles, very simple and beautiful in character, and to be perpetually lighted. Of those whose names are recorded over five thousand fell in army service, and some hundreds more in the navy, but the names of one hundred are included who were killed in the process of manufacture of guns and explosives at the Royal Ordnance Factory, and fourteen who lost their lives in air raids.

After the party had taken their positions on the dais, the chairman, Mr E H Kemp, read an address in which he referred gratefully to the generous local response which had been made, despite industrial distress, to the appeal on behalf of the hospital. The Council of King Edward's Hospital Fund for London had encouraged and urged the

completion of this, the first general hospital to be erected in the county of London since the war, and had given liberal support. It was hoped soon to announce that the entire cost of the building and equipment so far as it has at present gone—approximately £210,000, including the cost of purchase of land and of erecting the administration block—had been raised. Just over £200,000 of this amount is in hand, as well as £21,300 as an endowment fund to assist in future maintenance. Mr Kemp expressed the hope that the hospital would be regarded as the first link in a chain of such institutions on the outer fringe of the county of London, thus relieving the pressure on the older hospitals in the inner metropolitan area.

THE DUKE OF YORK, in opening the building, said that no more fitting monument could be erected to the gallant men and women of the useful town who laid down their lives in the war. He was glad to learn of the keen interest taken by the garrison itself in this work, also of the help given by the women and children of Woolwich. He praised a scheme of weekly collections on the hospital's behalf, and added that he would be pleased to learn that some of the great City companies, who are so generous in their allocations, were supporting a hospital taking patients who would otherwise go to increase the strain upon the older London institutions.

After a short service of dedication by the Bishop of Woolwich, the Duchess of York received gifts including several of £1,000 each to name a bed. One gift of £500, towards the cost of the x-ray and electro-therapeutic department, was presented by Dr John Clarke, on behalf of the medical practitioners of the Woolwich district. Another was a gift of £2,500 being a refund of the purchase money of half the grounds in which the hospital is situated, presented, in memory of his parents, by Major

ADMINISTRATION BLOCK AND PART OF THE FIRST SECTION

C E S Phillips, a past president of the Roentgen Society and well known for his contributions to x-ray physics. Dr W Cowie of Woolwich gave £50 for the purchase of ten wood chairs for the centric court, one of the local county secondary schools contributed £144 for apparatus for light treatment, and several elementary schools donations of £25 each for the equipment of cots in the children's ward. A further gift was a wireless installation, with headphones for each bed, and eight loud speakers, by the "Daily News Wireless for Hospitals" Fund.

A short description of the hospital appeared in the JOURNAL of May 14th (p 892), but reference may again be made to the spaciousness which is the first impression on the mind of the visitor. The cubic space allotted to each bed multiplies several times the minimum required by the Ministry of Health. Another feature is that all the arcades are laid out as Dutch gardens, and in this first section there are eight sun balconies, in addition to three lawns, making the hospital virtually a convalescent home. The hospital includes every modern device of heating and sanitary engineering. There is a red-tiled water tank on the roof of each ward, with a capacity of 8,250 gallons. Two Lancashire boilers have been installed to supply hot water and steam to all parts of the hospital, three calorifiers to re-heat hot water and steam supplies to parts remote from the power house, an economizer plant for partially heating the cold water supply to the boilers by means of waste steam, and a soot-blowing and flue-cleaning plant.

The population to be served by the hospital is approximately 300,000, but before the whole of the hospital is functioning that number may be very largely exceeded, owing to the new housing schemes which are developing in this locality.

### BRITISH MIDWIFERY IN THE XVIIth AND XVIIIth CENTURIES

PROBABLY few are aware of the fine chapter of British scientific progress and discovery, in the obstetric branch of medicine that is covered by the seventeenth and eighteenth centuries. It is one in which British medical men, whether obstetricians or not, cannot fail to be interested, and in which it is legitimate to feel some patriotic pride. That so little should be generally known is readily explained by the lack of a connected history of the period, such as is necessary in order to grasp the significance of the movement. The deficiency has now happily been removed by Dr Herbert Spencer's FitzPatrick Lectures which are evidently the outcome of many years of historical research; they are to be published shortly in a volume which will without doubt take a permanent place as a standard contribution to the history of medicine. Meanwhile a brief account of the result of his labours is published elsewhere in this issue (p. 853). Full justice could only be done to the subject by such a review of the movement from beginning to end as is related with freedom from partiality and with careful regard to accuracy as to the facts in the lectures. We may however here direct attention to one or two points which will serve to justify the inference which a perusal of the work compels—that our countrymen were the pioneers in the growth of obstetrical knowledge. At the commencement of the period it cannot be said that there existed any real knowledge of the mechanism of labour—the foundation of obstetrics. Normal deliveries were then undertaken not by practitioners, but by women who were generally ignorant actuated by trade considerations and devoid of all traces of the scientific spirit and male practitioners, who were consulted in the event of complications, can have had little or no experience of normal labour at all. For knowledge of the anatomy of the parts concerned in normal labour and of its mechanism we are indebted to the researches of Harvey, William Hunter, Ould and Smellie. As regards the mechanism of labour more particularly, it was Ould who first studied the subject in its true light as a problem in mechanics while the splendid work of Smellie carried the research to completion added to it the investigation of abnormal labour and gave to the world a conception of the process of labour which is recognized as the foundation of present knowledge. Again the means of effecting artificial delivery were at the beginning of the period extremely limited. The obstetrical practice of the time in its more favourable aspect is probably summed up with fair accuracy by Harvey when he recommends extreme forbearance and reliance on Nature in the conduct of normal labour and the adoption of podalic version in cases where any handiwork in the business is required. To this should be added in the hands of less conservative obstetricians certain measures mostly of a destructive kind.

The whole outlook of obstetrical practice was transformed by the invention of the forceps by Peter Chamberlen—one of the most beneficent in the whole history of medicine. Here again the invention was

followed up and brought to perfection in this country. Chapman dispensed with the pin having found that the blades locked firmly without it, Smellie invented the short form and (contemporaneously with Pugh, and Leviet in France) added the pelvic curve, and finally, by the invention of the lock produced what is essentially the form of instrument in use at the present time. Again in the management of the lying in room the old English obstetricians set on foot a series of reforms which quite obviously headed directly towards the aseptic and antiseptic treatment, and although eclipsed by the subsequent work of Pasteur and Lister theirs deserves to be remembered. The midwives who controlled the lying in room to the exclusion of male practitioners, though not universally lacking in intelligence, were under the influence of a bad tradition. Notions of cleanliness were crude in those days fresh air was diligently excluded from the patient and the over-heated lying in room by means of curtains and draperies, and the patient was plentifully doped with alcoholic erudles. On the supercession at the bedside of the midwives by the male practitioners these conditions underwent an immediate change for the better and Charles White Leake, and others gradually revolutionized the hygiene of the lying in room. Caudles and foul air were done away with, the close aggregation of patients discontinued, separate delivery beds instituted, cleanliness as regards the room, the patient and the attendants enjoined, and the attendants directed to wash their hands. In addition direct means were recommended with a view to combating infection, the lying in rooms were to be purified, and for this purpose the fumes of burning charcoal or sulphur were employed and the walls of the room whitewashed. What the old obstetricians understood by infection is clearly indicated by some passages in the records. It is stated that it may arise from putrid animal matter outside the body that the condition is in the first place an inflammation restricted to the uterus that the peritoneum becomes secondarily inflamed, and that the poison may act like a leaven and putrefy the whole body. When we add that there also existed a tradition introduced by Harvey and William Hunter, that treatment should be as far as possible conservative and that reliance should be placed on Nature in a process that is essentially physiological, it is obvious that English practice had its own marred characteristic features which were excellent in many respects. This was appreciated beyond this country, and there appears to be little doubt that Böer was influenced by it in his management of the great lying in hospital in Vienna. The low rate of mortality in that institution was the means of drawing the attention of Semmelweis to the hands of medical students as a source of puerperal infection and of his recommending the employment of chloride of lime as a disinfectant.

Dr Herbert Spencer has as far as the material allowed, introduced the obstetricians themselves to us in his lectures and many personal details add interest to the narrative. In some respects, indeed purely personal considerations were influential in moulding the course of events. This was the case with the Chamberlen family who acting apparently on the principle of beginning charity at home, carefully preserved the secret of their invention of the forceps retiring to the privacy of the closet and secreting the instrument beneath the boards when not in use. Not that they made a secret—on the contrary, they openly boasted of possessing a means of delivery surpassing in efficacy anything dreamt of by the midwives, and they

thereby reaped great credit for themselves. But the nature of the invention was bound to leak out, and when the secret became generally known among the male practitioners the midwives perceived that their business was in peril. The "halings and stretchings" with which they are stated to have tortured their patients were threatened by this secret and humane invention. Hence arose between the midwives and the male practitioners that battle royal which has already been graphically described by Dr. Spencer in a former work, and which inevitably ended in the discomfiture of the former at the point of the forceps, as one may say, the male practitioners remaining masters of the field, or bedside.

The profession, we believe, will be very ready to acknowledge the debt it owes to Dr. Spencer for introducing to it the old English obstetricians, with the names of many of whom we were unfamiliar—Ould, Osborn, Leake, Denman, Chapman, Aitken, Giffard, Manningham, the genial Maubray, and many more whose lives and works he has recorded.

### ERGOSTEROL, VITAMIN D, AND RICKETS

The progress of the investigations recently made with regard to ergosterol and vitamin D and the prevention and treatment of rickets has been noted from time to time in our columns during the last few months, and the scattered observations may with advantage be gathered together. The importance of the subject, both from the practical and theoretical point of view, fully justifies this.

Following on Hopkins's pioneer work, published in 1913, Mellanby, in 1919, suggested that rickets was a disease due to the absence from the diet of some accessory food factor, probably vitamin A. Other workers, particularly of the Glasgow school, contended that, since rickets could be prevented by fresh air and sunlight, there was no need to postulate the existence of any such accessory substance. The observation that rickets could be prevented, even in the absence of sunlight, by a diet containing cod-liver oil seemed definitely to establish the "deficiency" hypothesis, and the fact that cod-liver oil was still effective after the destruction of the vitamin A which it contained tended to prove that the factor involved was not identical with the latter. The existence, therefore, of another accessory factor had to be assumed, and to such a substance was assigned the name "Vitamin D."

Later work has justified both hypotheses. It was found, in the course of the post-war relief work at the Viennese hospitals, that children could be kept free from rickets or cured of the disease either by being freely exposed to sunlight, or by receiving a liberal milk ration, provided that the milk was obtained from cows that had been pasture fed. The milk of animals that had been stable fed on oilcake was comparatively ineffective. This "experiment" was the result of chance, in that the patients were under the control of separate groups of workers who held divergent opinions on dietetic matters. It therefore happened that in the case of one group of children attention was concentrated on the caloric value of the diet, while in that of the other particular heed was paid to the provision of accessory substances.

Not long after the Viennese results became available it was independently reported by two sets of workers that experimental rickets could be prevented if the food given to the animals was subjected to the action of ultra-violet light, although it was quite in-

active before exposure. Other observations show that animals fed on a rickets producing diet might be kept free from the disease if they were periodically subjected to the influence of ultra violet light. Apparently the accessory food substance and ultra violet light could each protect against rickets. The accessory substance must be included in the food, the radiations could act either through the food or directly on the body.

Chemical work had suggested that the accessory substance was associated, in foodstuffs, with that fraction which, though soluble in fat, could not be saponified by treatment with alkali. This "unsaponifiable residue" contains a number of substances, among them cholesterol. Chemically cholesterol is a complex alcohol, and is very widely distributed in nature. It is found both in animals and plants. It is relatively abundant in vertebrate nervous tissue. It occurs in the bile, and the bile acids bear to it a fairly close chemical relationship. It can be detected in the blood and its amount estimated. Probably it plays a part in fat transport and fat metabolism, and it is supposed that variations in blood cholesterol in certain morbid conditions are of diagnostic significance. In spite of the relative abundance in which it occurs, very little hitherto has been known of its function, and, in spite of much work, the details of its chemical structure are not yet established. It was shown, however, that if antirachitic foodstuffs were subjected to chemical fractionation the active substance was most closely associated with the cholesterol fraction. These observations led to the testing of cholesterol itself for antirachitic properties. It was found that cholesterol, apparently chemically pure, possessed none, but if it was exposed to ultra violet radiations it regained them. It was also found that there was an optimum period of exposure to ultra violet rays, at the end of which the maximum activity was developed. After this the potency, instead of increasing, actually fell off. Moreover, by chemical means, it was possible to recover 99.9 per cent of the rayed material as chemically pure cholesterol, incapable of further activation. Though the original specimen of cholesterol had fulfilled the ordinary chemical and physical tests of purity, the conclusion seemed inevitable that it had, in reality, contained traces of some other substance which, under the action of the light, had been changed into the vitamin. Though the recovery of 99.9 per cent as pure and inactivatable cholesterol showed that the amount of this substance must be very small.

A well known method of purifying cholesterol is to precipitate it as the digitonide. The fact that this process did not separate cholesterol from the substance then called "pro vitamin" suggested strongly that the latter must be a sterol. The fact that it is destroyed by bromine and other oxidizing agents as well as by over irradiation, suggests that it is a sterol of a highly unsaturated nature. It was observed that the spectrum of ordinary cholesterol contained certain very marked absorption bands in the ultra violet. These bands disappeared after irradiation, and this suggested that they might be due, not to cholesterol, but to the accompanying pro vitamin. It remained to discover the substance responsible for the absorption bands. A search among the sterols other than cholesterol brought to light the fact that the spectrum of ergosterol showed the bands of great intensity. Feeding experiments proved that irradiated ergosterol will protect rats from rickets in doses of less than one ten thousandth of a gram.

probably the minimal dose is in the neighbourhood of one fifty thousandth of a milligram.

Ergosterol is a sterol, first prepared from ergot. It is, however, as events have shown, very widely distributed. The work discussed has made it clear that vitamin can be produced from ergosterol the pro-vitamin, by natural or artificial ultra violet light, either in the animal's food or in its body. For the animal to secure a supply of this vitamin D two factors must be present—ergosterol and ultra violet light. It is evident that vitamin D must fulfil an important part in calcium metabolism. Where exactly, according to our present conceptions, it is to find a place is not yet clear, though it seems likely that its action is connected with the absorption of calcium salts from the intestine, but it must, of course, influence other factors besides absorption. There is every reason to hope that these discoveries will lead to the determination of the chemical nature of vitamin D but the problem is a difficult one—the chemical constitution of cholesterol is still obscure, and until that has been elucidated it is hardly likely that the constitution of ergosterol will be understood. At present no method other than irradiation is known for converting ergosterol into the vitamin.

#### CANCER OF THE LARYNX

The shades of Sir Felix Semon and Sir Henry Butlin must have been well pleased if they revisited the Royal Society of Medicine last week. It is as due to their efforts that the operation of laryngofissure became a well established procedure. At the Section of Laryngology on November 4th Sir St. Clair Thomson exhibited four patients on whom he had performed this operation respectively two and a quarter, three, four and a half and five and a half years previously for intrinsic epithelioma. These four patients were medical men, and all are now actively engaged in medical practice. They demonstrated better than any mass of statistics could do that this operation preserves a satisfactory voice and ensures lasting cure. The day before Mr. Lionel Colledge, in the Semon Lecture (of which we published a full abstract last week), showed that when intrinsic cancer has advanced too far for thyroid fissure a lasting cure can still be obtained by a complete laryngectomy. It is generally acknowledged on the continent that laryngofissure has been particularly studied in this country, thanks to the initiative in the last century of Semon and Butlin. It is a surprise to read that an American laryngologist who has performed a large number of complete laryngectomies should say, "as experience accumulates the sphere of the thyrotomy contracts." Sir St. Clair Thomson's unique experience in this operation has warranted him in asserting that, although laryngectomy is occasionally indicated for neglected and extensive intrinsic cancer, yet as such cases will become rarer with progress in the education of the public and the training of the laryngologist, so will laryngectomy become a less frequent operation, while laryngofissure will be more often performed and with greater success. As his statistics show, laryngofissure, if carried out with correct technique should be free from danger to life and should be followed by an adequate voice and lasting cure. As much cannot be said for laryngectomy. The President of the Section, Mr. Harold Barwell, in opening the session again urged the importance of both the public and the profession appreciating the necessity of obtaining a skilled laryngological opinion on any case of hoarseness persisting for more than three weeks. As this increases the sphere of laryngectomy will contract, and the brilliant results of become still more marked.

#### COLOUR VISION

SOME time ago the British Association appointed a committee "to report upon colour vision, with particular reference to the classification of colour blindness." It consisted of Professor Rort, who has recently been engaged upon original work in this subject, Dr. Mary Collins, whose book upon colour vision was reviewed in these columns about a year ago, and Dr. Edridge-Green, whose work upon this subject is well known, with Sir Charles Sherrington as chairman. The report summarizing their labours was presented to the British Association last September, and has now become available. Broadly speaking, its recommendations may be considered under two heads, the first dealing with nomenclature, the second with methods of testing. With regard to the first, it appears to be recommended that in the generic sense the term "colour blindness" should be dropped, and "hypochromatism" or "hypochromatopia" used in its stead. Two classes of defects are recognized—"blindness," denoting a decrease in sensitivity to a special region of the spectrum, and "confusion," denoting a decreased ability to discriminate different colours. It is suggested in the report that these two defects may occur separately. At present it is generally admitted that colour vision is a function of three variables (red, green and blue), normal people are therefore known as trichromats. In the largest class of colour-blinds one of these variables is absent and two only are present, these subjects therefore are known as dichromats. Those who see the whole of the spectrum as one hue (that is, the total colour-blind) are monochromats. The second group (that is, the dichromats) is subdivided into three subgroups—protanopes, deuteranopes, and tritanopes, corresponding respectively to the condition of red-, green-, and blue-blind, the terms being used descriptively and unprejudiced by any theory. These terms it is proposed to abolish, and the number of colours which are recognized in the spectrum taken as a measure of the degree of colour discrimination, after the manner of Edridge-Green's classification as penta-, tetra-, tri-, di- and mono- or a-chromats. Thus it appears that a patient would be classified on the following scheme—namely, as (1) red blind (that is, decreased sensitivity to light) from (say) 6,200 Å to the end of the spectrum and (2) as suffering from red yellow-green confusion. The old method of classification cannot be considered perfect but at least it was founded upon a very wide experimental basis. The same can hardly be claimed for the new classification, its dual nature, while certainly not adding to its simplicity, is probably superfluous. The report also outlines the methods recommended for the testing of the colour blind. First, sensitivity is measured by determining the threshold to light of different wavelengths. It is recommended that a spectral apparatus with a shutter for isolating a narrow region of the spectrum should be used, the intensity being varied by an episcotister or a photometric wedge. Two extremely important matters, however, are left out in the recommendation. It is by no means clear whether the "threshold to light" means the light (colourless) threshold or the colour threshold, presumably the latter is meant, for the achromatic (light) threshold in the colour blind is normal (König). Again, the report does not attempt to define the state of adaptation of the eye during the test—a most important and fundamental consideration in such a problem. With regard to the second question—the testing for confusion—it is recommended that it should be measured by the minimum change of wave-length which will produce a change of hue at two wave-lengths only—5,850 and 4,850 Å, a difference of over 50 Å being taken as standard. (Incidentally, such an examination itself would take several hours.) But it may be asked whether it necessarily follows that if subject thinks 5,900 and 5,850 Å (both in the γ

orange) are the same, he is going to confuse red and green. This, we are inclined to think, is the whole practical problem. Colour vision is notoriously one of the most difficult of physiological problems, and we cannot see that this report has gone very far to render the subject more comprehensible or its accurate detection more practicable.

#### AMERICAN HOSPITAL POLICY

ELSEWHERE in this issue we give an abstract of a report made to the Legislative Assembly in Victoria on hospitals recently constructed in Canada and the United States. The report is the result of a tour made by a delegation in order to gather information which should be useful to Melbourne, where it has been decided that improved hospital accommodation and better methods of training medical students are necessary. The delegation did not visit Europe, because it was believed that there it had not been possible to do much in the way of hospital construction since the war. Everywhere on the North American Continent the delegation found a well developed tendency to combine university, medical school, and hospital under one control. The report deals with the large hospitals only, which, with one exception, were found to be independent, or, as we should say, voluntary hospitals. Sometimes voluntary and municipal hospitals were combined, and then the voluntary management was supreme over both. They found one vast municipal hospital—the largest hospital in America—but it was the only one of the kind they saw. Its architecture, planning, and management did not impress them, "all the evils of political control being visible on every hand." Hospital reconstruction is the order of the day in the United States. In all the principal centres visited any hospital of more than fifteen years' standing was considered to be obsolete or obsolescent, and was either in course of rehabilitation or on the point of being replaced by a new building on another site. Amazing buildings are being erected—vast blocks, square set, towering into the sky, that call to mind the stern solidity of the ancient keep of Rochester Castle, but on such a Bismarckian scale as to make that ancient fastness seem no more than a sentry box, for these structures run to twenty stories high, yet all around there appears to be land enough and to spare. For the most part the hospitals charge their patients, some by fixed fees, some on sliding scales. In all there is a highly developed "social service department," the officers of which determine the patient's capacity to pay, and also play the part of fairy godmothers to the patient after leaving hospital. There is ample provision for the poor and for the rich, but there is a dearth of accommodation for the middle classes, the "white collar brigade," and serious efforts are being made to meet this deficiency. A phase of hospital work growing in the States is the use of scientifically trained dietitians. They are part of the regular staff. A difference of opinion is only found on the point whether there should be one diet kitchen for the whole hospital or one for each floor. This staff is responsible for the quality of the food, its preparation and distribution, and for furnishing the menu when a special diet is ordered by the doctor. It also teaches the nurses. Social service or almoner's departments are organized and financed as separate departments, with fully trained staffs, and there is association of social and philanthropic work and a reduction of overlapping in charities. Everywhere the delegation found the close association of medical teaching by university or medical schools with hospitals controlled by the schools, and where this did not actually exist plans for it had been made. In the schools there were very many laboratories for work and research, but few classrooms, and one great university had gone so far as to abolish the class system, and relied on the individual work of the student, but

therein was a rigorous selection of students and power to refuse inefficients. Stress was laid upon the necessity for separation of the teaching of undergraduates and post-graduates, the latter require specialties, the former do not.

#### THE COAT OF ARMS OF THE ROYAL SOCIETY OF MEDICINE

DURING the past fortnight or so Fellows of the Royal Society of Medicine will have noticed a change in the title page of the weekly diary and circulated from 1, Wimpole Street. The familiar though not very effective reproduction of the Society's seal has given place to a little less block of its new coat of arms. The history of this heraldic device is briefly as follows. Sir StClair Thomson, when he was President last year, felt that a Royal Society ought to possess a suitable coat of arms. He had already generously given the Society a beautiful old wrought gold presidential chain, and it seemed to him that a president's badge in keeping with it would make the thing complete. A committee was formed to discuss the matter, and an heraldic Achievement by Mr Martin Travers was unofficially submitted to the College of Heralds, who approved it without criticism. Formal application was then made in Sir StClair Thomson's name, and a Patent of Arms was issued in due course. A gold badge based on this design is approaching completion, and will be handed over by Sir StClair to

Sir James Berry, his successor in the presidential chain, at the annual dinner on November 16th. The technical description of the coat of arms is as follows. Arms, per pale vert and gules, the serpent of Moises or, entwined round a tau cross argent. Crest three sprigs of the herb "all heal" proper. Supporters, on the dexter side a representation of St Cosmas and on the sinister side a representation of St Damian both proper. Motto, "Non est vivere sed valere vita." The shield bearing the serpent is divided vertically, half being red, symbolizing surgery, and the other half green, for medicine. On the red side stands the surgeon holding a knife, and on the green side the physician with an Italian drug jar. The two figures are the martyrs SS Cosmas and Damian, who flourished in Italy in the early days of Christianity, and were adopted as the patron saints of medicine and surgery. They appear very largely in this capacity in Catholic Europe, and indeed also in England, for they were the patrons of the ancient Guild of Barber Surgeons, and are depicted in silver on the beautiful instrument case which used to be carried in the processions of the Guilds in the Middle Ages. The representation of these saints on the new coat of arms, which strikes us as pleasant and simple in its symbolism, is taken from a stained glass window in the Pazzi Chapel in Florence, the presidential badge consists of the shield done in coloured enamel and gold with the motto encircling it.

#### GERMAN ANTI TUBERCULOSIS ORGANIZATION

THE Italian Ministry is now engaged in an inquiry into the best method of combating tuberculosis on a national scale. The report of a commissioner, Dr Segri, who was sent to Germany, has recently been published, in which deals with finance, organization, and treatment. Tuberculosis was brought into the scheme of national insurance by a law passed in 1900, which enacted that all persons

<sup>1</sup> La Lotta Antitubercolare in Germania. By Dr. Arl. Segri. Bologna. L. Cappelli. 1926. (Sup. nos. 870, pp. 113. 1 figure. L. 1.)

affected with tuberculosis should be regarded as incapacitated from work and entitled to insurance benefit. In practice the scope of the law appears to be restricted to some extent, owing to the limited requirements as to notification existing in certain provinces. The scheme is financed chiefly by the national insurance department but substantial assistance is also derived from numerous communal and provincial benefit societies, from the clubs of the miners, railwaymen, and industrial and commercial workers, from the Red Cross Society, and from various religious institutions. The financial basis of the scheme is considered to be sound and its organization efficient. Contributions were readily forthcoming when it was realized that an extension of life for three years, or of working capacity for that period would effect a saving of 360 marks on each person insured. The organization of the campaign is in the hands of a central committee in Berlin with twenty-eight subordinate committees in various parts of the country. Their duties are to collect the necessary funds, co-ordinate economic and technical measures, establish new institutions, issue yearly reports on the working of the scheme, and carry out propaganda. During 1924 the funds administered by the central committee amounted to nearly 660 million marks. The organization comprises 1462 members, and consists of a presidium of thirty-three members, a committee of fifty, and a general assembly which meets annually. On the presidium and committee are several Ministers of State, presidents of medical and insurance societies, bankers, hygienists and others occupying public positions. Notification is made in the first instance to the health authorities established in the cities, and from these the cases are reported to the local tuberculosis dispensaries (Tuberkulosefürsorgestellen) which are the advanced posts in the campaign. The primary function of the dispensaries is to make the diagnosis, ascertain the type of the disease, and prescribe the appropriate treatment and to this end they are provided with a skilled personnel and a complete up-to-date laboratory equipment. If domiciliary or ambulatory treatment is considered desirable this (Heilfürsorge) is superintended by the medical director of the dispensary. The dispensaries have the equally important function of scrutinizing the hygienic condition of the patient's home and the state of health of the inmates (Heimfürsorge), and in case the latter run any risk of infection, of procuring the isolation of the patient either in a separate room or in some anti-tuberculosis institution (Wohnungsfürsorge). The functions of the dispensaries are therefore mainly diagnostic and prophylactic. Where institutional treatment is indicated, a distinction is made between cases considered curable within three months and those requiring more prolonged treatment. The former are sent to sanatoriums situated mostly in the mountainous districts of the country and at present capable of accommodating 24,400 patients. Some difficulty seems to be experienced in clearly distinguishing the cases suitable for sanatorium treatment and a considerable proportion of unsuitable cases gain admittance to these institutions. This is recognized as a defect in the system, which requires correcting. More protracted cases are admitted into special hospitals for tuberculosis, into the tuberculosis wards of the general hospitals, into convalescent homes, and open air institutions.

#### PRESENTATION PORTRAIT OF SIR BERKELEY MOYNIHAN

SIR BERKELEY MOYNIHAN, Bt President of the Royal College of Surgeons of England was presented on November 7th in the Lord Mayor's Rooms, Leeds, with his portrait in oils, painted by Richard Jack, R.A., and subscribed for by his friends and admirers in that city. The Lord Mayor, Alderman Hugh Lupton, made the presentation, and the

portrait is to be hung in the board room of the Leeds General Infirmary, with which Sir Berkeley Moynihan was connected from the time he was house-surgeon until last year. The gift was also a recognition of his work for the School of Medicine of the University of Leeds, in which he has been professor of clinical surgery since 1909. There was a large attendance of professional colleagues, pupils, and other friends, and expression was given to the high regard and affection in which Sir Berkeley is held by the Lord Mayor, Dr Wardrop Griffith and Mr T. F. Braime, who accepted the portrait on behalf of the Infirmary.

#### UNIVERSITY OF LONDON MEDICAL GRADUATES SOCIETY

As will be seen from a statement in our column of university intelligence it is proposed to constitute a University of London Medical Graduates' Society and thus add another to the already considerable list of clubs and societies recognizable by the Senate. In addition to such are the various political associations within the University and there are, or were, certain dining clubs, as well as the University of London Club in Gower Street. While there are no doubt adequate grounds for seeking to bring together more closely the graduates in medicine of the University, circumspection will be necessary in two directions if the success which we wish for the new society is to be achieved. It will be incumbent on the promoters to avoid needless overlapping with other long established medical societies for whose membership all medical practitioners are eligible and caution will be required not only in avoiding ordinary political activities but also those questions of university politics which have often so sharply divided the alumni of the University of London.

#### THE ROYAL SOCIETY

The Copley Medal of the Royal Society has been awarded to Sir Charles Sherrington, O.M., G.B.E., M.D., for his distinguished work on neurology. A Royal Medal has been awarded to Sir Thomas Lewis, M.D., for his researches upon the vascular system following upon his earlier work on the mammalian heart beat. The Buchanan Medal has been awarded to Professor Major Greenwood for his statistical researches and other work in relation to public health. The following medical names appear in the list of Fellows recommended by the President and Council of the Royal Society for election to the Council on November 30th: Treasurer, Sir David Prain; Joint Secretary, Dr H. H. Dale; other members of Council, Dr E. D. Adrian, Sir Hugh K. Anderson, Sir Archibald Garrod, Professor J. C. G. Ledingham, and Professor G. Elliot Smith.

As we have already announced the International Congress of Otolaryngology will be held in Copenhagen next year from July 30th to August 1st. To assist those attending it from this country a British Committee has been formed with Sir James Dundas-Grant as president, Sir St. Clair Thomson as chairman, and Messrs Lionel Colledge, J. S. Fraser, and F. W. Watkin-Thomas as honorary secretaries. Mr Sydney Scott is acting as treasurer and to him (130 Harley Street, W.1) should be sent the subscription of 5s. In return members of the British Committee will be kept informed of all arrangements with particulars of travelling to Denmark and the stay in Copenhagen. The committee is open to all members of the profession.

The King has nominated Sir W. Leslie Mackenzie, M.D., for reappointment as a member for Scotland of the General Medical Council for five years from October 28th, 1927.

## HOSPITALS IN AMERICA

## AN AUSTRALIAN DELEGATION

MELBOURNE, the capital city of Victoria, Australia, is exercised about the state of its hospitals. There is need for increased accommodation, and medical opinion demands better methods of training medical students than present arrangements allow. A committee was appointed which made certain proposals, including aggregation of the main hospital accommodation upon eleven and a half acres of land contiguous to the University in the northern part of the city. To ascertain the tendencies of modern hospital construction a delegation of three—Dr. the Hon. Stanley S. Argyle (Minister of Public Health), Mr. R. J. Love (Inspector of Charities and Secretary of the Hospitals and Charities Board), and Professor R. J. A. Berry (Dean of the Faculty of Medicine)—was appointed to visit America. Its report,<sup>1</sup> which was presented recently to the Legislative Assembly, begins by stating that "the priority of new construction in Europe during the past twelve years renders almost obligatory a visit to the United States on the part of those contemplating new buildings if they wish to be furnished with modern construction, equipment, and organization." The Rockefeller Foundation planned the tour of the delegation. New Zealand and Canada were also visited.

The report is of great interest, not only for what it has to say on the matter of buildings, equipment, teaching arrangements, and training of nurses, but also because it tells something of the quality of the patients and the terms on which they are admitted to hospital.

There were at the beginning of this year in the United States of America 6,946 hospitals with 859,445 beds and in Canada 458 hospitals with 62,500 beds. Hospitals used for teaching medical undergraduates number 316. Forty of these are owned by the medical schools of the universities, and a further thirty-seven are under their control. In about one hundred others some teaching is given. "Hospitals are no longer regarded only as institutions for the cure of the sick and injured, but as essential elements in the education of the community with regard to the causation, prevention, and cure of many of the diseases which afflict mankind." The average length of the medical course is four years, but there is a pre-medical scientific course of two years, many schools demand one year's work as an intern, and some are now requiring six months' work with an approved general practitioner in private practice. Some States require a further examination before practice is allowed. The American Medical Association has done a great piece of work in certifying hospitals fit for the reception of interns; these number 578, with 4,952 posts. Besides, there are others for special work. Students are subject to selection before admission to the schools. Of 20,000 applications made in the States and Canada last year only 6,500 were accepted.

## Vancouver

The University is eight miles from the city in a park of 600 acres. It has also a vast landed estate, which it may sell or lease. The city is expected to grow to the University, and a hospital will be built there. At present there is a town hospital of 900 beds.

## Toronto

The general hospital has 742 beds, and will shortly have 1,000. It has special departments, and a "workmen's compensation ward." Its revenue is £213,000, all, with the exception of £19,000 from endowments and subscriptions, derived from fees paid by or for patients. The hospital is opposite the University, and the staffs are associated. In the children's hospital of 250 beds it has been found in the past that 75 per cent of infectious diseases in the nursing staff arose in the isolation block. There are now glass cubicles and the nurses are masked, and infection has dropped to negligible proportions.

<sup>1</sup> Report on the Coordination and Correlation of Hospital, Medical Schools and Research Institutions in Canada and the United States of America. By Dr. the Hon. Stanley S. Argyle, M.B., M.R.C.S., M.L.A. Ordered to be printed August 16th 1927 by the Legislative Assembly of Victoria. Melbourne Government Printer. 1p. 37. Price 1/6d net.

## Rochester, N. Y.

Close to the University is the Strong Memorial Hospital, endowed by the Rockefeller Foundation and Mr. J. P. Morgan of Kodak fame, at the cost of £3,000,000. It is on a site of sixty acres. There are here two hospitals together—the voluntary and the municipal, making 430 beds. The two hospitals have one management and apparently one staff. Only members of the hospital staff may treat patients. An aerial photograph shows vast squared blocks of connected buildings some six stories high. The charge for a bed in a four bedded room is five dollars a day, and theatre and radiology fees are extra. There are private rooms at ten to fifteen dollars a day. In the latter cases professional fees are charged extra. The medical school is within the buildings, with clinical and pre-clinical laboratories (that is, anatomy and physiology, etc.), and there is a separate residential house for the junior staff. The school of dentistry is combined, and half a mile away are the fever, mental, and tuberculosis hospitals. The bacteriological laboratories comprise those of the University and of the city.

## Boston

Boston is famous for Harvard, the wealthiest private university in the United States. Its funded property is worth £15,000,000, and it spends \$235,000 a year on its medical schools. The medical school is three miles from the University and adjoins a large teaching hospital. Others in the city are also used for teaching. The Massachusetts Hospital which was founded in 1811, has two distinct parts: one for the poor, the other a "community" hospital—that is, for paying patients—where fees from five to fifteen dollars a day are charged. The fee to the doctor, who must be a member of the staff is extra. This pay department is distinct from the general hospital though under the same management, it has its own kitchen, theatres, and dispensary. It has 106 beds, and is eight stories high. Need is felt of some intermediate provision for middle class patients, and this is being arranged. More than half the cost of the whole hospital is met by patients' payments.

## Yale University, New Haven

The medical school is new, and opposite the hospital which is to be rebuilt. As in other American schools, it was noticed that "few lecture rooms were provided, but an abundance of research laboratories." Insistence is made here on the fundamental necessity for housing pre-medical sciences close to the clinical schools. The scheme of the outpatient department presented some novel features. The patient makes an appointment with an officer of the institution to be examined by the physician or surgeon. "Stragglers" without appointment are seen last, 90 per cent come by appointment. There are no hours of waiting in outpatient halls. Since the department is called a "dispensary," and the name is in ill odour it is to be changed to "clinic for ambulatory cases." In the school a rigid selection is practised, only 50 per cent of the students desiring admission are accepted, some 15 per cent are asked to withdraw as inefficient. The class system has been abolished, students may work more or less as they please, and the final examination determines whether the time of the student has been well or ill spent.

## Columbia University, New York

Columbia University is quite separate from the clinical schools which are scattered through the city. But the defects of this plan are felt, and concentration on a site of twenty acres is planned. By agreement the University and the Presbyterian Hospital are building a colossal hospital and medical school at a cost of £4,000,000. It appears to be an enormous structure, some parts of which are twenty stories high. Mount Sinai Hospital is described as being old (some parts of it were built fifteen years ago!), there are 600 beds, and patients pay from £2 10s a day upwards for maintenance. The need for middle class accommodation is felt, and is being met. In the city the delegation found one critic of the concentration tendency. Dr. Dougherty, the director of the Jewish Hospital, "considered that the tendency would prove of more value to the specialist than to the general practitioner."

## Philadelphia

Here is the University of Pennsylvania the oldest in the States. University, medical school, and hospital combined so long ago as 1873. The staff of the hospital is

University faculty. It has 550 beds (73 maternity). In the general hospital were found for the first time the large old wards of twenty five beds. But it is to be rebuilt at the charge of the city. The theatres are faced with marble, which is held to be cheaper in the end than tiles. Here is a food handling clinic where all persons engaged in handling food in the city are regularly examined, it is part of the city public health work.

#### Baltimore

Again at the Johns Hopkins Hospital and School, Baltimore rebuilding was in process. There was also co-operation between the hospital and city authorities. An aerial photograph shows a vast series of blocks some running to ten or twelve stories high and yet there is ample land all round. Of the patients received into hospital, for each one that pays in full four do not, 46 per cent paid nothing, and 78 per cent less than full cost. But it is claimed the arrangements are identical for all classes of patient, with the exception of the private room. In the school each department occupies one whole floor, each has its own animal room. There are numbers of small laboratories, and few lecture rooms.

#### Detroit

In this city of great works, containing as it does the Ford and Dodge factories there are four hospitals, but none are teaching institutions. The Ford Hospital is not for the employees of the Ford works but for private patients, it receives patients at a charge of 18s to £1 12s a day for nursing and maintenance, and from 4 to 14 guineas a day for professional services. There are additional fees for radiology, theatres and pathological work. The building cost £220 000. Of the four hospitals one is maintained by the city for the poor.

#### Ann Arbor

At Ann Arbor, forty miles from Detroit, is the home of the University of Michigan. The residential population is 25,000 but there are 12,000 students, for whom there are ten departments in the University. In the last four years the State has spent £2,000,000 for new buildings. The hospital belongs to the University, and cost 1½ million sterling. There are 1150 beds. All the patients pay or are paid for. The staff is full time and not allowed private practice, either in or out of the hospital. There are ten acres of floor space and two miles of corridors, twenty wards of eighteen beds each, thirty six two- or four bedded rooms, and many private rooms for which the charge is ten dollars a day. In one corridor there are eleven operating rooms, two set in pairs with common service rooms. There is communication between all parts by pneumatic tube, so that patients' records are sent through without delay. There is a heart centre with an electrical recording device connected with all parts of the hospital. In the theatre attached there is a similar arrangement whereby all the 150 students listen simultaneously to the heart beats of the patient under examination. The plans and elevation of this minor city hospital are truly amazing.

#### Chicago

The medical school of the North Western University is being rebuilt at the cost of £1,000,000, the gift of a lady in memory of her husband. The building is in the heart of the city on land reclaimed from the lake. It is fourteen stories high. The first seven and the fourteenth comprise the medical school, the rest the dental school and research quarters. There is no hospital on the site but two are to be built to give 1,100 beds. The patients will pay on a sliding scale according to their means as certified by the social service department. The cost will be £1 a day. At present medical teaching is carried on in ten hospitals in the city here and there and the defect is apparent. Six miles out of the city is the Chicago University and its new medical school with a hospital. A noble structure is being erected to combine all under one roof.

Cook County Hospital is an institution the like of which was not found by the delegation elsewhere. It is maintained by the Cook County of the State of Illinois. There are 2,600 beds, a number which is being increased to 3,200 the ultimate aim being 4,000. The bulk of the staff are part time (twenty hours a month) in an honorary capacity. There are sixty six interns who serve eighteen months. Students from the University of Illinois attend here for their fourth year. The patients are all supposed to be indigent poor and pay nothing for maintenance or treatment. There are no outpatients. This is

the first free hospital maintained and managed by a county council that I have seen. It did not impress me with its architecture, planning and management, all the evils of political control being visible on every hand.

The delegation also visited the Mayo Clinic at Rochester, Minnesota, which has often been described. The general conclusion reached was in favour of the proposal for the reconstitution of the Melbourne medical school, and of the desirability of combining and correlating the hospitals, medical school, and research institutions in one site, contiguous to the University.

## A CLINIC FOR PHYSICAL TREATMENT IN LONDON

In a previous issue (September 17th, p. 502) we referred to a proposal to establish in London a clinic for physical treatment (primarily for insured rheumatic persons), on the lines of those already existing in Berlin and elsewhere in Germany. We have received the following memorandum from the secretary of the London Clinic Subcommittee, British Committee on Rheumatism (International Society of Medical Hydrology, 6, Bentinck Street, W.)

### I—The Problem

According to official statistics, more than 370,000 individuals under the National Health Insurance Act alone seek relief annually from the pain practitioners for rheumatic diseases. London has an insured population of 2,400,000. There are therefore many thousands of rheumatic persons who require treatment in London.

There are many varieties of disease included under the general term rheumatism.

(1) Acute forms which confine the patient to bed (a) rheumatic fever (b) acute rheumatoid arthritis, (c) the more acute forms of inflammation of fibrous tissues. With these the clinic would not deal—it is an *ambulatorium*, not a hospital. The patients must be able to walk or be fit to be brought to it.

(2) Subacute forms (a) in the soft tissues—lumbago, sciatica, fibrositis, etc., (b) in the joints (arthritis) and periarticular tissue.

(3) Mechanical impediments which follow acute or subacute attacks, or disability due to accident or injury.

The object of the clinic is (a) To treat the subacute and chronic forms of rheumatism and prevent the development of mechanical disabilities. (b) To attempt to resolve the exudations and adhesions which have already formed, to restore the patient's working capacity and to alleviate many conditions that cannot be completely cured. A large proportion of persons affected with rheumatism are still at work, and it is believed that many more might remain at work if they could be treated at the clinic after working hours. (c) To carry out systematic investigations.

### II—Means at our Disposal

In general the patient will have at each visit two or more of the following methods applied in succession, and this combined treatment will be continued, usually three times in the week for from two to four weeks, slight cases requiring only brief treatment. These physical methods do not necessarily exclude other forms of medical or surgical treatment.

(1) Heat and cold and movement in water, vapour, and hot air—locally and generally applied.

(2) Manipulation and exercises alone or in combination with heat by the hand or by douches or whirling water.

(3) Radiation—as heat light and invisible rays (ultra violet and infra red) from arc or mercury vapour or other lamps.

(4) Electricity—as constant current to resolve exudations and promote nutrition, as interrupted current to cause movement of muscle fibres and as high frequency current (diathermy) to raise the temperature of deep-seated parts.

Like many drugs, physical remedies are sedative or stimulant.

(1) Subacute cases require warm application of water or vapour and gentle manipulation. These are sedative remedies, they relieve pain and allay congestion and nervous and circulatory excitement.

(2) Chronic cases require brief and intensive application of heat, with strong manipulation. These are stimulant remedies.

The value of periodic physical treatment in such cases is illustrated by the fact that at a recent visit to the clinic at Amsterdam a young man with spondylitis deformans was accepted for a second course of light baths, and a train of 30 with progressive muscular atrophy, for a second course of electric baths, both of which had been "greatly relieved and able to carry on a fair previous treatment." A young woman a "centimetre" with arthritic polyarthritis and much crippling was reported as carrying on her work with the assistance of a course of baths every year.

By causing active hyperaemia and increasing the circulation of blood and lymph and the local nutrition they help to remove the effects of former disease or injury. They act also powerfully on and through the skin, and indirectly on the nerve centres and general nutrition, by stimulating elimination and metabolism. Cold douches and sprays are also used as stimulants to the nerve centres and metabolism.

### III—A First Demonstration in London

It is proposed that the clinic shall be made available for men and women patients, whether insured or not. Such clinics have proved their value in other countries, and have for many years formed part of their national health insurance systems. The institution of physical clinics is, moreover, justified by long experience at our spas, where external methods, by mineral water and by plain water, combined with other physical procedures, are systematically employed for out-patients and other persons affected with rheumatic and chronic or incipient diseases.

A demonstration clinic in London will serve (1) To familiarize the medical profession and the public with the value, scientific use, and combination of physical methods. (2) As a centre for many lines of investigation—for example, on the functional disturbances occurring in early cases, on causation, on the influence of occupations, and on therapeutic classification.

A certain proportion of cases will, upon examination, prove to be unsuitable for an out-patient clinic. Arthritis, for example, can only be properly treated by baths at a certain phase in the disease. Others will be referred for hospital or dental treatment, and others for spa treatment at one of the British spas. The suggestion that such a clinic would be a "London spa" is incorrect. A spa is a health resort with specific waters, for those who need or can afford a complete change as well as treatment. Medicinal waters cannot be synthetically prepared.

Following the experience of the Continental city clinics for insured persons, provision is to be made for a normal estimated number of not less than 400 cases a day. Allowing for an average period of three weeks' treatment, this will provide for between 11,000 and 12,000 individual cases per annum. It is stated that 300 cases a day are treated in the small clinic at Amsterdam, 700 to 900 a day in one of the friendly societies' ambulatories or clinics in Berlin, and about the same number in the fine clinic at Dresden.

Such a mass of clinical material will necessitate the appointment of a medical director and staff having expert knowledge of physical methods of treatment. The medical director and his colleagues, who will be responsible for the various departments—hydrotherapy, light, ionization, etc.—must be experienced in diagnosis and in those modes of treatment. Clinical assistants and trainees, paid and unpaid, will be required for the daily work of the clinic. It is proposed to begin the operations of the clinic on a modest scale, but in premises which can be easily adapted to accommodate increasing numbers of patients. Tabulated reports, showing the number and nature of the cases treated and the results, will be periodically published. It is anticipated that young practitioners and attendants will be trained at the clinic for undertaking similar work elsewhere.

It is recognized that the systematic combined use of physical methods on a large scale will be to some extent a new thing in medical practice in England. The proposed clinic will be founded with the definite purpose of providing facilities for concurrent investigation and treatment for incipient, subacute, and chronic diseases, particularly for rheumatic diseases in insured persons, and also for the results of injuries. It should be and will be, conducted in the spirit of co-operation with the voluntary hospitals and with the British spas.

## England and Wales.

### EXTENSION OF SHEFFIELD ROYAL HOSPITAL

THE new out-patients' department of the Sheffield Royal Hospital has been formed by converting a chapel adjoining the hospital, and includes a spacious waiting hall, medical and surgical examination and dressing rooms, and departments for ophthalmology, otology, rhinology, and laryngology. A small operating theatre, a research laboratory, and a dispensary are also provided on the ground floor, on the first floor is a new operating theatre for minor operations, together with an anaesthetic room and recovery room and a lecture room for the use of students and nurses. Mr F. M. Osborn, chairman of the board of management of the hospital, stated that the total expenditure on the new department would amount to nearly £20,000. During last year the daily average number of persons visiting the

out-patient department was 700. The Minister of Health, in declaring the department open congratulated the Sheffield Joint Hospitals Council on the good work it had done in securing co-operation and furthering economic and noted with satisfaction that the penny in the pound scheme was now yielding £100,000 a year for current needs. Mr Chamberlain emphasized the preventive aspect of the work in out-patient departments, and suggested that further improvement was possible in facilitating co-operation with general practitioners. The Minister also opened a new maternity and child welfare centre in Sheffield, which had been erected at a cost of £15,540, he commented on the fact that infant mortality had been more than halved in the town during the last twenty-five years. The attendances at the old centre for the first nine months of this year numbered 589,000, as compared with 550,000 for the whole of last year. Systematic visiting of children between the ages of 2 and 5 had also been instituted, and during the small-pox epidemic in the early months of 1927 the visits that had been paid to homes numbered 2,665.

### TUBERCULOSIS IN LANCASHIRE

During 1926 the death rate from pulmonary tuberculosis in Lancashire was the lowest on record for the fourth successive year. Low records were reached also by the death rate from non-pulmonary tuberculosis and the number of notifications of new cases of pulmonary tuberculosis. This may be contrasted with the fact that, during the ten years before the war, there was in this county little or no decline at all in the deaths from pulmonary tuberculosis. In his report for 1926 Dr G. Lissant Cox, the central tuberculosis officer of the Lancashire County Council, expresses the opinion that far fewer cases of tuberculosis escape being notified in that county than in many other parts of Great Britain. This great improvement in notification is attributed to closer co-operation between general practitioner, the local medical officers of health, and the tuberculosis officers. Dr Cox directs special attention to the value of heliotherapy and x-rays in the diagnosis and treatment of tuberculosis. As to heliotherapy, it has been found best that the patients should be treated three times each week, with an interval of at least one day between exposures. In a series of ninety-one patients at the Ashton-under-Lyne centre in whom the disease became quiescent and apparently cured, the average duration of the light treatment was rather under ten months. Previous to heliotherapy these patients had had an average of sixty-three months' treatment by other methods. At the Lancaster centre the average duration of treatment by light of fifteen patients was three months, as compared with an average of thirty-eight months by other methods of treatment previously. Dr Cox comments on the economy of time and expense which would seem thereby to be obtained. Heliotherapy was found to give very good results in lupus and in adenitis with abscess formation and skin involvement. It is emphasized that each patient requires individual care and attention as regards the initial dose and the gradation of exposure, a test radiation should precede treatment in order to determine the sensitivity of the skin. No permanent ill effect, either local or general, followed artificial light treatment. The county possesses nine x-ray plants, five being situated in dispensaries and four in county sanatorium hospitals. The number of skiagrams taken during 1926 was 4,791, as compared with 4,115 in the previous year. Dr L. Fagan Stewart contributes to the report a number of skiagrams of interesting pulmonary cases with clinical descriptions. He regards the x-ray examination as part of the clinical examination, the diagnosis being based on all the evidence available. In the earliest stages of bone and joint tuberculosis a skiagram may fail to reveal abnormality, but in tuberculosis a skiagram may suggest the presence of disease, though clinical symptoms suggest the presence of disease of the hip, this is said to apply especially to tuberculosis of the hip, knee, and spine. The absence of x-ray evidence cannot therefore, be accepted as contraindicating the existence of early tuberculosis. The use of x-rays was found particularly helpful in detecting such non-tuberculous conditions as early osteo-arthritis of the hip, early spondylitis deformans, Kohler's disease, and Schlatter's disease. Besides helping diagnosis, skiagrams of patients at intervals during treat-

ment made clear what changes were occurring, and sometimes determined whether operative intervention was required. Dr Stewart strongly advises that in all cases of non-pulmonary tuberculosis a skirgram of the chest should be taken, since a pulmonary lesion is frequently found which has become quiescent and does not give rise to symptoms. It is proposed to make a further study of the behaviour of such pulmonary lesions in the combined case.

## Scotland.

### EDINBURGH CITY AND THE UNIVERSITY.

THE question of financial assistance from the city of Edinburgh to Edinburgh University was raised at a meeting of the Edinburgh Town Council on October 27th in connexion with a speech which had been made at a recent graduation ceremony by Principal Sir Alfred Ewing. He had adverted to the help given to English universities by municipalities, and asked whether it was possible for the Corporation to assist the University of Edinburgh to a greater extent than it did. Treasurer Guest said that the question was not new. The relation which existed between the Corporation and the University was good, and at the present time the Corporation regularly assisted the University in two ways by means of a fixed annual payment of £2,170, and by relieving the University from liability to pay burgh assessments which was a very valuable concession. The Corporation also from time to time made special grants in response to special appeals. It was pointed out that while in England a large municipality exercised the function of the education authority and could thus impose rates for the purpose of giving grants to universities, in Edinburgh the education authority was a separate body and independent of the Corporation. An education authority in Scotland had power to make grants to universities which would be payable out of the rates, but the corporations of cities had not this power.

### EDINBURGH RECTORIAL ADDRESS.

Sir John Gilmour, D.S.O., M.P., Secretary of State for Scotland, before he delivered his rectorial address to the students of Edinburgh University, received the degree of LL.D. from the Chancellor, the Earl of Balfour, who recalled that the recipient was an old student.

The Lord Rector, after noting the healthy and gratifying growth of the University's social activities and of the number of its chairs and lectureships proceeded to deal with the development that had been associated with science and medicine. Every faculty, he said, had expanded greatly in recent years but the lion's share of this expansion had fallen to science and medicine, studies which came in contact with one another on many points. The last hundred years had witnessed a tremendous change in man's attitude to Nature and an immense increase in his command over natural forces. The islands, small as they were, had produced a large proportion of the men by whom this progress had been made possible. The names of intellectual giants like Faraday, Darwin, Lister and Kelvin leapt to the mind at once. Towards the close of his long and memorable career Lord Kelvin was reported to have said that his chief regret in growing old was that he could not hope to live to see the wonders which he was certain that the twentieth century would reveal. In the years that had elapsed since his death much had happened to justify his forecast. What Britain needed more than anything else at the present juncture was men and women of learning who had mastered the main principles of the new knowledge and had grasped the importance of applying this to the things of everyday life. From the time of their foundation the universities had had a preponderating effect in moulding our civilization through their influence on what was highest in the intellectual life of the people. They were now called upon to assume a higher responsibility than ever. It was their increased activities on the practical side that touched the general body of the nation most nearly. Improved health and increased prosperity were the fruits for which we looked to the seeds now being

sown in the laboratories. The strategic front of medicine had changed more and more. Its real aim in the future must be not to cure but to prevent—not to remain passively on the defensive and await the onset of disease, but boldly to assume the offensive. That depended, of course, on a very close observation of symptoms in individuals but it demanded also what medical research had been giving in increasing degree—a knowledge of the nature of the organisms to whose presence diseases were due, as well as of the means by which their ravages could most effectually be checked. The first achievement of Pasteur had been to save the silk trade of France by identifying the two diseases of silkworms and by showing how their germs could be detected and destroyed. His second was his demonstration of a simple means for securing immunity of sheep and cattle against anthrax. Research along similar lines into other animal diseases and plant diseases was full of potentialities for good. That was why the Lord Rector welcomed so heartily such developments as the Rowett Research Institute at Aberdeen and the new chair of animal genetics in Edinburgh. Knowledge had travelled far beyond the point which Virgil had reached when he wrote his *Georgics*, and there was still a long road ahead. He concluded by saying that what all could do was by diligently using their own minds and by earnestly seeking to extend their own opportunities to others, to help to swell the tide, on the force and set of whose currents depended the prosperous voyaging of humanity. After the conclusion of the address a luncheon was held in the University Union, at which the Lord Rector referred to the great record the University had behind it, and said that that record was as nothing to the record which was before it, that was in the hands of the younger generation. In the evening, Principal and Lady Ewing, supported by Sir John and Lady Gilmour, held a reception in the library of the old University. A dance was organized by the Students' Representative Council in the McEwan Hall.

### ANIMAL BREEDING RESEARCH DEPARTMENT, EDINBURGH.

The seventh annual report of the Animal Breeding Research Department of Edinburgh University gives a record of the work done in the new institute established during the past year at West Mains Road, Edinburgh. Dr F. A. L. Crew, director of the department, states that about thirty acres of land are at present used for the maintenance of experimental animals, while the department uses six laboratories in the neighbouring chemistry block of the University. The function of this department is to secure and democratize knowledge concerning the physiology of reproduction and inheritance, with special reference to the animals of economic importance. Lord Woolavington recently donated £10,000 towards the endowment of a chair of animal breeding in the University, and this department is managed under the joint control of the University and of the East of Scotland College of Agriculture. It has been in existence on a small scale since 1920, and recently received an offer of £30,000 from the International Education Board, contingent upon a further £30,000 being provided by the University and other private sources. Much work has been done in connexion with the study of sheep's wool, experiments having been in progress regarding the inheritance of various colours and patterns. It has been established, among other things, that a dominant black colour exists in the Black Welsh Mountain breed of sheep as well as in the Pechald breed while a recessive black is common to several breeds. Various recessive patterns have also been studied. A peculiar malformation of the limbs, found in lambs which are usually born dead or die soon after birth, has also been studied and found to be a definitely heritable character. Experiments have been continued in regard to the analysis of the Clydesdale breed of horses. Some 1,500 pedigrees have been tabulated and examined. It has been shown that remarkably little inbreeding has taken place in the Clydesdale. Work on cattle has also been continued, which is mainly a matter of collecting data for several years and analysing results. Data regarding the inheritance of the dun colour have been collected, and are almost ready for publication. Partial sex transformation

in cattle has been recorded, as this department had previously found to exist in the case of poultry. Work dealing with superfoetation in pigs and the increase of winter milk production in goats has also been in progress. In regard to fowls, experiments have been carried on regarding the duration of fertility in eggs, the role of the thyroid in determining characteristics, and the relation between and plumage, as well as numerous other points. As regards other laboratory animals, a study of calcium metabolism has been carried out in the rabbit, the migration of the ovum has been studied in the rat, ovarian implantation in the mouse, and some facts regarding the attitude of the wings in Polish flies. An appendix gives a bibliography of the various publications which have been issued from this department.

#### VACCINATION PROSECUTIONS IN EDINBURGH

Three prosecutions as the result of parents refusing to allow their children to be vaccinated were heard recently at Edinburgh Sheriff Court. In one case the father, on being asked to plead, began a statement to the effect that vaccination had never done any good, that his refusal was not a crime, and that there was no offence of this nature on the Statute Book. The sheriff intervened, and stated that if the man did not plead properly in answer to the charge he would be committed for contempt of court, whereupon the refusal to allow the vaccination was admitted. In each case a fine of 25s was imposed, including 15s expenses.

#### WORK FOR THE CRIPPLED CHILD

At a lecture and demonstration in the Music Hall, Edinburgh, arranged by the Edinburgh Association of the Chartered Society of Massage and Medical Gymnastics, Miss Gertrude Heifeld, F.R.C.S. Ed., who presided, said that a massage clinic had been established at the New College Settlement in Edinburgh, where 1,023 treatments had already been given to poor children under the direction of a medical officer, the fees being graded according to the circumstances of the patient. Miss Margaret Morris of the School of Dancing, London, gave an exhibition of remedial exercises with the help of members of her staff. The basis of this work, she said, lay in combining remedial exercises with an appeal to the artistic sense in the production of harmonious movements. If dancing did not help everyone to stand, walk, and breathe better it missed its aim. Dame Agnes Hunt, D.B.E., R.R.C., the founder of the Shropshire Orthopaedic Hospital, said that slumps and bad food were responsible for nearly one-half of the cripples. Next to prevention in these matters came early treatment. Almost all cripples could be taught to earn their own living, and this ideal had to be set before the mind of every cripple.

#### HEALTH LECTURES FOR INSURED PATIENTS

At a meeting of the Insurance Committee for the city of Edinburgh, held on October 27th, arrangements were discussed regarding a proposed series of health lectures by doctors on the committee's panel to their own insured patients. It was reported that, following on the resolution of the committee to provide courses of lectures, a number of doctors in the city had been approached and had agreed to participate in the scheme. The general idea is that each doctor should lecture to an audience of his own patients only. The committee agreed to arrange meantime for four lectures by doctors in various parts of the city as an experiment. In order to ensure that the lectures would be prominently brought before the insured persons concerned, an invitation to attend the lectures would be issued by the committee to every patient on the lecturer's list.

#### SCOTTISH SERBIAN HOSPITAL

A public meeting was held on October 26th in the hall of Queen Margaret College, Glasgow, to appeal for funds on behalf of the Children's Hospital in Belgrade. The hospital had been founded by Dr Katherine Maephail, a Glasgow graduate, and was said to be the only hospital for children in Jugoslavia. A committee representative of women's organizations in the West of Scotland was appointed to raise money for the institution. Miss David

Mason, wife of the Lord Provost of Glasgow, who presided, said that the hospital had become not only a centre for child welfare work but now also a training school for Serbian nurses. The Marchioness of Aberdeen spoke of a visit to the hospital last year and of the sympathy which Serbian women felt for this country, and of their hope that this hospital would not be abandoned. Dr Katherine Maephail, the original founder of the hospital, said that she and her staff were working hand-in-hand with the Serbian Government, but foreign support had been greatly diminishing, and for some years the main support had come from the "Save the Children" Fund in London. The Serbian Ministry of Health was very anxious that the work should continue, and British support was very necessary for this.

#### PROPOSED HOSPITAL FOR HADDINGTON

During the course of last summer an appeal was made by a local committee in Haddington for a sum of £7,000 to provide a cottage hospital for Haddington and the surrounding district. Towards this a sum of £2,881 has already been collected. Mr John Vert of Pendleton, Oregon, U.S.A., who had been born in Haddington and was the son of a former provost of the burgh, had intimated his desire to give £7,000, the sum necessary to erect the building. Conditions attached were that the hospital should be called the "Vert Memorial Hospital," and that the committee should undertake to make every effort to raise at least another £7,000 for a permanent endowment fund. Mr Henry Vetch, a local proprietor, also offered to give one acre of ground as a site for the hospital. A donation of £1,000, from Mr Frank Hoisburgh, Cleveland, Ohio, a former resident of the burgh, was announced.

## Ireland.

#### MEDICAL REGISTRATION IN THE IRISH STATE

The first meeting of the Irish Free State Medical Registration Council, constituted under the Medical Practitioners Act, 1927, was held on November 1st in the board room, Government Buildings, Dublin. The Minister of Local Government and Public Health, General Mulcahy, who was accompanied by Mr McCarron, secretary to the department, and Dr Stephenson, chief medical adviser, received the members, all of whom were present. Their names were given in this column on October 29th (p. 800). Dr Denis Coffey was unanimously appointed President of the Council. The Council proceeded to consider the steps necessary for the establishment of the *Free State Medical Register*. Under the Act the Register must be established not later than May 28th, 1928.

## Correspondence.

#### "WEST AFRICAN YELLOW FEVER"

SIR,—I was glad to observe that in your note on yellow fever in West Africa (October 29th, p. 798) you did not fall into the error, which appears to be now common, of using the term "West African yellow fever," which implies that there are at least two varieties of that disease, a fact which has not, so far as I am aware, yet been proved. In conversations, in 1924, with Surgeon General Carter, U.S.A. (the greatest authority, then living, on that disease), at Kingston, Jamaica, and also in Panama, he expressed a very decided opinion that West Africa, and not the West Indies, was the original home of yellow fever. If this view is accepted "yellow fever" is the proper name for the disease as it appears in West Africa, and no qualifying adjective is necessary.

In a paper by Oskar Klotz and Winifred Simpson in the *American Journal of Tropical Medicine* (vol. vii, No. 5, p. 271), entitled "Jaundice and the liver lesion in West African yellow fever," I find the following:

"Intensive studies upon yellow fever have been made upon the Western Hemisphere and the clinical data and logical findings which have given us the picture of the disease have been based upon observations made in the Americas."

also. Only a few pathological reports upon spread of the not dealing with the disease as a whole have been published by Steven on Turnbull, and Seidlin in relation to the disease known as yellow fever in West Africa. (The initials are mine)

This, I submit, does a great deal less than justice to the work and reports of the Yellow Fever Commission (West Africa), appointed by the Secretary of State for the Colonies in 1913, of which the late Sir William Leishman, Sir Ronald Ross, and Sir William J. Simpson were the original members, and of which I had the honour to be chairman.

The reports of that Commission and of the investigators who were sent out to West Africa, among them was the late Mr. Broot, dealt very fully and exhaustively with the disease in all its respects, and I am not aware of any important additions to our knowledge of that disease which have since been made, with the exception of those for which we are indebted to the late and grievously lamented Adrian Stokes.

I note in the paper just mentioned the following:

It is not our purpose to discuss the parallelism of the lesions of the various organs in fatal cases occurring in Africa and in America. Suffice it to say that in a pathological study of the materials from thirty-five fatal cases taking place in Nigeria and the Gold Coast we were led to conclude that no fundamental difference was to be noted.

An erroneous bacteriological observation would appear to be an inadequate reason for a change in the name of a disease.—I am, etc.,

JAMES K. FOWLER,  
Chairman late Yellow Fever Commission  
(West Africa)

London W. 1.

#### WATER SUPPLY AND IODINE IN RELATION TO GOITRE

SIR—In your issue of September 24th (p. 559) you say: "There is a tendency to consider that deficiency diseases are almost synonymous with avitaminosis." To this view exception is taken, and you state that deficiency of certain inorganic salts in the diet amongst them iodine, may give rise to disease. The mention of iodine presumably refers to endemic goitre. I would refer your readers to the issue of January 15th (p. 24), where McCarrison states that deficiency of iodine had no relation to goitre in the Sanjour school. McCarrison has recently published (*Indian Journal of Medical Research*, 1927, vol. xv) a paper on "The experimental production of a new type of goitre unrelated in its origin to iodine," in which he recapitulates the present position with regard to the relation of iodine to goitre. In speaking of the various types of goitre produced by him experimentally, he says:

With the possible exception of those caused by the administration of cultures of fecal bacteria the goitres produced in this way are preventable by increasing the intake of iodine proportionately to the hygienic conditions of life of the animals or of the excess of fats or of lime in their food.

In the examination of a series of 84 samples of soil taken from different parts of Derbyshire I found that the limestone soils contained an average of 59.0 parts of iodine and the gneiss soils an average of 18.0 parts of iodine per 10 parts of soil. Yet it is on the limestone, and particularly these places deriving their water supply from this formation that colloid goitre has in the past been so prevalent.

The examination of the iodine content of water supplies derived from the limestone and the millstone grit shows that the absence or presence of iodine in these waters in no way related to the present prevalence of goitre in districts depending on them. My own survey work in Derbyshire has shown that there is approximately three times as much goitre of a marked character in children drinking water from the limestone as in those who drink water derived from the millstone grit and if these places which draw their water from deep borings in the grit, which certainly tap water from the limestone underneath, were excluded the marked relation between goitre and drinking water derived from the limestone would be still more obvious.

But there are exceptions to the rule on both sides which have puzzled me greatly, and it is only on reading McCarrison's paper that I have been able to put upon

the solution. He proves very conclusively that deficiency of vitamins A, B, and C in the modern diet of the people, and particularly vitamin B, even in the presence of abundant iodine, can give rise to a type of goitre hitherto undescribed.

In view of the confusion which exists in regard to the causation and prevention of the thyroid diseases included under the generic term simple goitre the results of the experiments are illuminating. If it seems likely that the type of goitre here described be found to occur sporadically among the white flour-eating peoples then the view that all simple goitres are due to iodine deficiency and preventable by the prophylactic use of iodine must be abandoned. The experimental evidence here produced makes it probable that in western countries this new type of goitre will be encountered in its progressive stage in childhood and in young women whose food contains much vitamin poor carbohydrate, little suitable protein and less green vegetables and fruit, and in its retrogressive stage in older subjects whose food has similar faults. If this should prove to be so iodine will neither prevent nor cure the disease but a well balanced diet rich in vitamins will.

It is interesting to note that Otto Steiner in 1924 came to a very similar conclusion concerning goitre in some parts of Switzerland. The subject is one of importance in practical medicine, and McCarrison's paper is deserving of the widest notice.—I am, etc.

HEANOR DERBYSHIRE Oct 26th PHILIP H. J. TERTON, M.D.

#### CONVULSIONS DURING GENERAL ANAESTHESIA

SIR—I have read with great interest the discussion on epileptic convulsions occurring during ether anaesthesia reported in the *BRITISH MEDICAL JOURNAL*.

In my recent book *Epilepsy* (German edition, J. Springer, Berlin, English edition to be published shortly by Bailhere Tindall and Co.) I have been able to assemble evidence afforded from experimental work on animals and from clinical cases which goes to prove that the period of transition from unconsciousness to consciousness as in waking from sleep, is the period *par excellence* for the occurrence of epileptic phenomena. Further, a latent tendency to epileptic manifestations is frequently betrayed for the first time at this period. Although the example quoted relates to the normal experience of transition from unconsciousness to consciousness—that is, waking from sleep—the period of transition from unconsciousness induced by a narcotic, by suffocation from immersion in water, strangulation or other accident to consciousness, is associated with the same tendency as regards the demonstration of epileptic phenomena. The evidence afforded seems to me to suggest the question: Why are epileptic manifestations so comparatively rarely seen in persons emerging from anaesthesia?—I am, etc.,

ALAN CRIDAM, M.D. L. J. J. MUSKENS

SIR—I note that in his letter in the *JOURNAL* of October 29th (p. 886) Dr. Pinson adheres to his original suggestion as to the cause of ether convulsions—that is, that they are "the outcome of the extensive action of the CO<sub>2</sub> in patients who are sensitive to this naturally and who are under the influence of ether." This still seems to me hardly adequate to fit all the facts. Why, for instance, have they only appeared during the last few years? I can find no reference to them prior to the articles by Dr. Pinson in the *JOURNAL* for May 28th and the late Dr. S. R. Wilson in the *Lancet* of the same date, and all the cases quoted are comparatively recent. Either used to be frequently given in circumstances much more favourable to high CO<sub>2</sub> concentration when closed inhalers were more in vogue. Why have they appeared predominantly in Manchester, where the bomb is probably used more extensively than elsewhere? Dr. Pinson cites eleven of his fifteen cases as occurring with the bomb and the only other experience of true convulsions which I have seen reported occurred with the bomb. It may be a matter of pure coincidence but it seems to justify investigation on the lines I suggested.

As regards chest complications I can only say that Dr. Pinson's experience has differed from mine.—I am, etc.,

CHAS. W. NORRIS, M.D. H. P. FAIRLIE

*Epilepsy*, Part I ch. 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100.

# CONVULSIONS DURING LOCAL ANAESTHESIA

SIR,—I have read with interest Dr Liston's letter on this subject in the *BRITISH MEDICAL JOURNAL* of October 29th (p 806)

On March 6th, 1925, I extracted the right upper lateral incisor of a man of about 40 years of age. The local anaesthetic used was locosthetic, a preparation containing 0.75 per cent. of cocaine hydrochloride and one part in 50,000 of adrenaline chloride, and the quantity was something less than the recommended dose of 1 ccm., which contains one ninth of a grain of cocaine. After waiting three or four minutes after the injection the extraction was carried out without difficulty or pain. The patient rinsed his mouth with two tumblers of water in succession, and then, probably 10 to 15 minutes after the injection, he had a violent epileptiform convulsion. He lost consciousness, his breathing became stertorous, and his skin and conjunctivae assumed a jaundiced hue—not purple, as in Dr Liston's case. In this condition the patient kicked a bracket table, two feet higher than the seat of his chair, and drove it through a plate glass window.

A few seconds later he recovered, but was not able to leave the house for an hour, at the end of which time I sent him home under escort in a taxi cab.

He stated that he had never had a fit before. On two occasions since 1925, using novocain, I have extracted teeth for this patient, without any unpleasant results—I am, etc.,

London, W1, Nov 1st

A J MAURICE, L D S Ed

## MANAGEMENT OF MENTAL DEFICIENCY

SIR,—The report of the Board of Control must interest greatly those engaged in mental deficiency work. Taking the remarks seriously

1 I agree entirely as to the good results obtained from institutional treatment, provided the cases go there early enough. Those institutions are undoubtedly better planned in which patients are disposed in separate blocks, such as Monksall, and, in the case of simple epileptics, at Chalfont St Peter. This arrangement allows of much more accurate classification, and has several other considerable advantages not touched upon in the report. I am convinced that any prospective colony should be arranged upon these lines.

2 *Marriage of Defectives*—This is so obviously undesirable that no comment is needed.

3 *Sterilization*—While at once admitting that the operation, in its most successful issue, would not obviate the necessity of institutions, I believe that suitably selected cases would relieve pressure elsewhere and afford many cases the greater freedom they can reasonably claim. While agreeing with most of what Dr Turner (Report, p 44) says, I still think that a minority, however small, have a claim to special consideration both on their own account, and also for financial reasons. I refer to this point again in my memorandum upon hostels.

4 *Ascertainment*, however accurate, is not to be considered an end in itself. It is equivalent only to requiring ground for a colony and in proceeding no further. Ascertainment in Devon is commendably high. I think I may say that all engaged in the work here take this as a strong incentive to renewed activity for some tangible results to their labours.

5 *Supervision* to a certain extent is the supplement to ascertainment, and, pending increased institutional treatment, is perhaps the best means of keeping in touch with known defectives. The size and geographical nature of Devon, however, make both ascertainment, and especially supervision very difficult—more so, I fancy, than is realized by the Board of Control itself.

6 *Occupation centres* are admittedly excellent, and do much both in reaching those cases for which institutions have no room, and those whose parents are unwilling to send them from home. We have few in Devon, and, were there more, access to them would be difficult unless special transport facilities were provided. The want of them might conceivably be met by setting up special classes in some of the smaller towns and larger villages.

7 *Guardianship*—I do not share the Board's optimism with regard to this scheme. It is most difficult, often impossible, to get the right sort of guardian in the right locality. Most cases suitable for modified "discharge" require great care in the choice of environment in every sense of the word, and it is most difficult to combine suit-

ability as regards patient, guardian, environment, and accessibility. The ideal solution of the difficulty of providing for leave of absence and discharged cases lies in the selection of hostels. These would afford the patient a feeling of personal freedom and change, combined with the knowledge that he or she was at least a partial wage earner, would relieve the ratepayers by producing a class of partial wage-earner, and would afford a feeling of safety, as to the disposal of patients, to the authorities concerned. I am quite aware of the difficulties involved in the scheme, but most difficulties can be overcome. For instance, in the more rural districts agricultural and road work might replace the usual work of the more ordinary hostel. I may also remark that sterilization might usefully be employed in many cases suitable for a hostel.

8 *Mental Deficients in Mental Hospitals*—I agree that this is in every way undesirable. Should the ordinary inmates in any way become aware of the presence of idiots and such-like, the effect upon their unbalanced minds might be devastating.

9 *Encephalitis Lethargica*—There is little doubt that we are now seeing many results of this in police courts and elsewhere. In looking over reports from our school medical inspectors I am much interested to note quite a number of children, classed dull and backward, who have definitely or indefinitely suffered from this disease. I am keeping a special record of these cases in order to be able to compare their past and future histories. I am doubtful whether these cases should be returned as normal to an ordinary school, though a large number of them are certainly not certifiable under the Mental Deficiency Act—I am, etc.,

Exeter Nov 6th

CLAUDE A P THURMAN

## CONTRIBUTORY SCHEMES HOSPITAL CLUB PRACTICE

SIR,—In your issue for October 22nd last (p 751) you refer to a scheme proposed for Birmingham which, in its injustices, fairly beats all other schemes so far heard of. You express an opinion on such schemes which happens to be on all fours with statements made by myself at the July Meeting of the Representative Body (*BRITISH MEDICAL JOURNAL*, SUPPLEMENT, July 30th, p 75), and it is a matter of surprise that so far no one has commented on that opinion. It is this:

"Contributory schemes are forms of insurance. They are just as much insurance as the insurance of one's house against fire. There is a tendency in some quarters to attempt to disguise this fact by a haze of philanthropic zeal on behalf of the hospitals. Such zeal is right and laudable, but it should not be allowed to blind the critical eye, so that it fails to scrutinize the details of the policy of insurance which is enacted under the guise of contributory schemes. A lack of care in the initiation of these schemes may mean a world of trouble later on, and possibly strained relations between the authors of the schemes, the hospitals, and the contributors, which might be avoided by a little cool criticism at the outset."

Everyone who concentrates on this question must agree with your statement, especially had you referred in the sentence to the "private practitioners." No distinction can be drawn between a scheme for the provision of domestic medical attendance for services within the competency of a general practitioner and another scheme for services which, as a rule, are beyond his competence. Both are forms of "club practice," however hidden under a euphemism. Under both the premiums paid should be adequate in order to make a reasonable payment to the practitioner for the services guaranteed by the scheme. If a practitioner refuses payment it does not make any less a case of club practice, whilst he lays himself out to the accusation that he is underselling his profession to his colleagues, for, in fact, he places himself on some lower plane than the doctor who opens a house to his patients for sixpence (with medicine nuncupate) in a district where half a crown is recognized by all as reasonable. And yet at the moment this is the attitude of many visiting staffs of hospitals.

The policy of the Association states distinctly that the beneficiaries under these insurance schemes are not to be considered objects for charity, but that the full cost required to pay, by adequate premiums, the full cost of

benefits offered and received. The policy also depreciates the conduct of such schemes by hospitals. But here, unfortunately, the reasons which would appeal to the profession are not stated and, if known would show that the proposal is especially pernicious. By conducting such schemes of club practice the hospitals are intentionally robbing in, and offering to provide in their club, many medical services which equally well, and with every consideration for the best interests of the patients, could be given either at the patient's home or at the private house of the specialist and be paid for direct.

By acquiescing in clubs conducted by hospitals the visiting staffs in areas where there are in addition to themselves medical practitioners able to give such services are not only foregoing for themselves legitimate fees, but are whilst being subsidized, underselling their competitive practitioners, and are therefore—possibly unknowingly—acting in a manner which all must own to be derogatory to our profession. When voluntary hospitals are taken over by the State, or when the provision of "additional medical benefits" for those in these clubs becomes a State concern, it will be very difficult for the visiting staffs to explain why from the State they should expect any more in form of payment than the kudos with which they were content when they served the clubs run by or for the voluntary hospital authorities.

The general practitioner and medical specialist not on the staff of a hospital complain that they are being undersold, that their patients who can pay full fees are being deprived, in consequence of this loss of practice, of that up-to-date skill and experience they are entitled to, and that all this is harmful to the public weal.

At the present moment many hospitals are further extending their out-patient and specialist departments—the necessity for which is in great part brought about by the to-be expected increased demand for free attendance consequent on the formation of these clubs.

It seems to be very little appreciated, even amongst those placed highest in the Association's organization how greatly these clubs are making inroads into what should be private practice and increased private practice.

The policy of the Association which would meet all the difficulties of the situation is succinctly stated in the resolution appearing on page 74 of the *SECRETARY'S* of July 30th last. If the visiting staffs of voluntary hospitals would bestir themselves and, linking up with the Division (or Branch) organization of the Association, thrash out an application of that policy which would apply to their area, securing its acceptance by their governing body, it would prevent the trouble, friction, strained relations and discussion in our profession which are likely to extend and to which you refer—I am, etc.,

Here Nov 5th.

E ROWLAND FORTHEGILL

### HOSPITAL POLICY

Sir—Mr Connell in his letter of October 8th (p 651), is to be congratulated on bringing to the front facts which are either not known, or, if known, deliberately kept in the background in discussions on hospital policy. As a general practitioner I venture to mention a few points and express a few opinions which, I think will lend support to the statements contained in Mr Connell's letter.

It is common knowledge, at least in this part of Birmingham that Dudley Road Hospital has become within the last five years, the best and most progressive hospital in the city. Why is it that a Poor Law hospital has so suddenly and so quickly emerged from "infamy" prejudice into such a high post on in popular estimation?

The reasons are not far to seek. To the wage-earning class the first question that arises when hospital treatment is required is: How soon can it be commenced? The people desire to get into hospital as soon as possible while at the same time they demand the highest standard of

treatment. It is erroneous to believe and imagine otherwise. Dudley Road Hospital meets these requirements.

The voluntary hospitals, on the other hand, are quite incapable of dealing with the large number of patients requiring hospital treatment in Birmingham. True, the number of beds is limited, but it is strange that if a patient is in a position to pay a consultant a fee beforehand, he can, in my experience obtain admission within a day or two of the day on which the consultation took place. If no fee is forthcoming, his name is put down on the waiting list, the period of waiting being anything from six months to three years. Such a long wait is both irksome and irritating to a working man, and tends to lead to a state of mind which is certainly not conducive to improvement in his general health.

Many get tired of waiting and ask me to send them to Dudley Road Hospital. Many, knowing too well of the difficulty of getting admitted to a voluntary hospital, ask me to send them to Dudley Road Hospital, while many—I think I could say most—now express a keen desire to go to that hospital.

In view of these facts it is little wonder that most of my patients receive hospital treatment, when required, at Dudley Road Hospital, it is the hospital of choice. I am able to get them admitted in either of two ways. First, by giving them a note to the relieving officer. Secondly, by giving them a note to attend the out-patient department of the hospital. The second method is new, and is due to the formation of a splendid out-patient department by the medical staff of the hospital. All emergency cases are admitted by the first method, and all less urgent cases by the second.

Mr Connell, in my opinion, is rightly indignant, and is fully justified in saying that Mr Herbert Eason's deductions are erroneous as regards Poor Law hospitals, and in particular as regards the hospital under discussion. I have no hesitation in saying that no hospital, either teaching or non-teaching, works with a higher professional standard or at a higher pressure than Dudley Road Hospital.

It is true that the medical staff can devote most of their time to the work of the hospital—they are not dependent on private practice for a livelihood—but it is far to have this hospital, which I maintain, is working at as high a pressure as a voluntary hospital and is absolutely essential to the general practitioner and the public, understaffed while the voluntary hospitals, which are not able to meet the demands made on them by the general practitioner and the public, would appear to be oversuffed? I do not think this is fair, but it will continue as long as the medical profession clings to the voluntary system.

Why does the profession cling to the voluntary system? Surely it is honest enough to realize that it is a system which can never supply the needs, in proper fairness, of the public, and to acknowledge that, at present, the Poor Law hospitals are making a great effort to meet those needs. These efforts are entirely on the part of the medical staffs, and I feel that they are to be congratulated on fighting such a hard battle, for they are opposed by a Poor Law system which tends to hamper and retard progress, and they are not receiving from their own profession the support and recognition they deserve.

Let us as soon as possible have a unified hospital system, but do not let us make the mistake of having it controlled by either a voluntary medical staff or a well meaning but incompetent lay body—I am, etc.,

Birmingham Oct 23rd

WILLIAM MCC MACPHERSON

### DENTAL RADIOGRAMS IN DIAGNOSIS

Sir—Mr Badcock's letter of October 22nd (p 755), on dental radiograms in diagnosis, raises a question of the utmost importance to both medical and dental practitioners. Very few would disagree with the statements made but the issue is much wider I believe, than the interpretation of dental radiograms. The relation between the doctor and the dentist certainly could be improved.

A greater knowledge of dental pathology would appear to be the solution for all practitioners. The dentist cannot know a special form of pathology without being more

<sup>1</sup> The resolution referred to is as follows: That the visiting medical staff of hospitals should seek to secure arrangements with boards of health for the allocation of recognition of their services in accordance with Section XII of the Voluntary Hospitals (United Kingdom) Policy of the Association since any laxity in securing such recognition is detrimental to medical work of all kinds and ultimately to the general public.

widely recounted than at present with the general principles of the subject. The medical practitioner has little opportunity of acquiring knowledge of dental diseases, the curriculum for any examination does not demand such knowledge, and, if demanded, hardly any examiner under the present arrangements is capable of conducting such an examination.

The number of medical students attending the dental departments of the hospitals for information, beyond that of extraction of teeth, is remarkably few. In fact, for the most part, medical men know nothing of dental diseases or their pathology. The commonest interpretation is that discoloration constitutes disease, frequently have I known a tooth stained black by the application of silver nitrate to be regarded as the worst tooth in the mouth. These remarks may be thought too severe, but I would not have them so interpreted, for until recent years only the few have regarded pathological changes connected with the teeth as of great importance.

What seems to have happened is that the medical practitioner, possessing in radiograms his only form of information upon dental conditions, has credited them with an excessive value, whilst the dentist, with a limited knowledge of pathology, has done the same.

Stereoscopic radiograms, when obtainable, are of greater value than simple films or plates, but each is made through such a thickness of bone that unless a marked change has resulted little information can be derived.

In the future some knowledge of dental conditions must be acquired by all medical men. The next issue, therefore, is educational. Can the curriculum be extended? I feel sure the time will come when all special departments will have to be attended and a separate examination conducted upon the elementary principles of each of these special subjects—I am, etc.,

London, W 1, Nov 1st

W WARWICK JAMES

#### "THE HISTORICAL ASPECTS OF QUACKERY"

SIR,—I should like to thank Professor Clark for assuring me that his remarks were not to be applied to the general body of doctors using Abrams's methods in England, but also to remind him that my misinterpretation of his words was perfectly excusable since he chose to bracket qualified doctors with quacks. On this account I maintain that his attitude really remains as indefensible as ever. I have sufficiently laboured the point that no qualified doctors, not even Abrams, can legitimately be bracketed with quacks by Professor Clark just because their views appear mistaken to him. Scientific criticism is possible without doing this sort of thing. For example, his views may also appear mistaken. If he had an intractable disease, and cures of which he observed to occur as the apparent result of a weird procedure, he would try that procedure himself, and his chief motive, as he well knows, would not be in underlying belief in magic. For this and other reasons I regard his views on the historical aspect of quackery as largely mistaken, but I do not therefore scorn them and bracket him with quacks. So far as I can see, escape from my criticism is only possible if he shows that I am under another misapprehension and that his remarks on quack practice were not applicable to any persons who possess or possessed medical qualifications equal to his own, whatever the nature of their beliefs.

I await his reply with interest, in the hope that I may be proved still further mistaken in my interpretation of his remarks—I am, etc.,

London W 1, Nov 5th

J KENELM REID

SIR,—With experience should have taught Professor Clark that in getting out of an untenable position he should act as a man with all due apologies. He now seems to have dropped both Abrams and Hahnemann, but he cannot get out of his head his idea, and that of nobody else, "that all diseases can be both diagnosed and treated by means of two boxes containing some simple electrical apparatus." He knows perfectly well that Abrams never confined himself to "two boxes," but was always trying something new. He often said that a problem solved is a problem dead, and rushed off to something else which his fertile brain saw

required solving. He did much more investigation of psychology than my friend Dr Kenelm Reid who at last has extracted a feeble apology from Professor Clark.

Some of Abrams's latest work was much on the lines as that of Dr Bissky. They were both investigating psychology on a physical basis and, *inter alia*, that determined when a man is speaking the truth. Although Professor Clark was, I believe, in London during the two visits of Dr Bissky I have not heard of him or any other person from Tavistock Square attending any of Dr Bissky's demonstrations. So far as I know there is only one of Dr Bissky's diagnostic apparatus in this country, and that is in the possession of an Abrams practitioner.

However simple the boxes may be in Professor Clark's estimation, they work, and that is the great point. There is no standing still in Abrams's methods any more than there is in wireless. Marconi says, "we are just entering what may be called the field of vibrations, a field in which we may find more wonders than the mind can now conceive."

Abrams tried hard to abolish the personal equation and substitute a mechanical contrivance for the human subject. Bunnell is at present working on the same line, but personally I am very doubtful about the nit of man ever being able to produce anything so delicate and reliable as the human nerve reflexes. We have always had the artist and the copyist, the latter should try as far as possible to imitate and emulate the former.

I would advise Professor Clark before he again ventures into print to try and get a knowledge of the subject with which he is dealing, and before again attacking Hahnemann he should see Dr Boyd of Glasgow, who will teach him a little physics as well as homoeopathy—I am, etc.,

London, Nov 4th

JAMES BAIR

#### ULTRA-VIOLET RADIATION AND VARICOSE ULCERS

SIR,—Dr Dore's letter (October 22nd, p 757) raises the following points: (a) My comments in the *BRITISH MEDICAL JOURNAL* of September 10th (p 472). (b) The indiscriminate use of actinotherapy and exaggerated statements of the results. (c) The role of ultra violet radiation in the treatment of varicose ulcers.

(a) My comments were made to draw attention to the wide divergence of opinion among dermatologists as to the value of actinotherapy. The following summary of the views of dermatologists who took part in the discussion on Dr Dore's paper at the Annual Meeting of the British Medical Association (*JOURNAL*, August 13th, p 255) will make this point clear.

*Chronic Septic Ulcers*—Dr S T Dore Benefited by ultra violet radiation. Dr F Gardner Useful. Dr A C Foxburgh Most useful.

*Pyrexia (Adults)*—Dr Gardner Aggravated. Dr W J O'Donovan Improved.

*Itch*—Dr O'Donovan Doubtful. Dr Gardner Improves. Dr Dore Inferior to x-ray.

*Psoriasis*—Dr O'Donovan Very occasional benefit.

*MacCormac* Very variable results. Dr Gilchrist (USA) Mystical. Dr Dore Little permanent improvement.

This difference of opinion amongst dermatologists is not confined to the above meeting. More instances can be quoted—for example, *Proceedings, Royal Society of Medicine*, March, 1927, Section of Dermatology, p 45 (558).

*Pyrexia of Bacter and Ravel (Adult)*—Dr O'Donovan Longed light therapy most successful. Dr G B Dowling Never seen any remarkable result from even six months treatment with the quartz lamp.

These differences of opinion, it is suggested, are due to differences in technique adopted by the above observers. None of them, however, actually mentioned what technique had been adopted in the different conditions treated. If the technique had been similar the results would have been more uniform.

(b) This is too big a subject to be adequately discussed here. The worst offenders are the people who have bought lamps, their training and knowledge of the subject being obtained from a manufacturer's pamphlet. If a lamp, it must be used on every part of the body and to justify its use good results must be obtained.

(c) Dr. Dore admits that varicose ulcers benefit by ultra-violet radiation, but evidently does not consider that it should be adopted as a routine method. What are the contraindications? All varicose ulcers are septic. All varicose ulcers are surrounded by skin with defective nutrition. New epithelium must be stimulated to grow over all ulcers. If ultra-violet radiation is of value in these three factors in some ulcers why not in others? It may not be necessary to resort to ultra-violet rays in small recent ulcers, but the problem is the large chronic ulcer in which the old methods have failed even when the patient is at complete rest, and where surgical intervention has given no relief.

With ultra-violet radiation I have succeeded in healing ulcers which had remained open in spite of continuous treatment for periods varying from twenty-four to five years—I am, etc.,

London W1 Oct 24th

M. WEINBERG

#### PAROXYSM OF AURICULAR FIBRILLATION

SIR,—Dr. Arthur Stephens has done well to draw attention to the singular communication of Dr. Brewis, under the above heading in the *JOURNAL* of October 1st (p. 595).

In this letter a case, diagnosed as auricular fibrillation, is described as exhibiting an impulse in the auricular area which could be both "seen and felt", further, that "the auricular systole was distinctly heard". Auricular fibrillation is a morbid state which shows us disconnected contractions of the individual auricular fibres, the result of which is complete paralysis of the auricle. It is possible that the contractile power of the fibres is undiminished, and that the paralysis results not from lack of power output, but solely from lack of concerted action. As it stands, Dr. Brewis asserts that a paralysed auricle yields an impulse which can be seen and felt, and is audible, *quod est et videtur*, for he will not contend that the fibrillary contractions will be visible, palpable, and audible.

From a clinical standpoint it would be better if cases of auricular fibrillation were labelled paralysis of the auricle—the consequence or inco-ordination of the fibrillary contractions—this so far as the auricle itself is concerned. We know, however, that at a pinch the circulation can dispense with the auricular systole, and that our concern, as physicians, is rather with the irregular action of the ventricle which attends upon the auricular fibrillation, and which may seriously impair the ventricular output, but that is another matter—I am, etc.,

London W1 Nov 5th

HARFINGTON SAINSBURY

#### PYREXIA DURING THE PUERPERIUM

SIR,—The legislative distinction between fever and pyrexia to which Dr. Hebblethwaite draws attention, is indeed a cause of confusion. Surely no one will deny that these words differ only in their derivation, the one from Latin, the other from Greek. Any dictionary confirms this.

Would it not be simpler to add the word "major" or "minor" to whichever of the two specified degrees of puerperal febrility—call it fever or pyrexia, as you will—has to be noticed? Statistical and administrative purposes would be equally well served, and the philologist would not be left wondering—I am, etc.,

B. FRASER BENSON, M.R.C.S., D.P.H.,  
Major late I.M.S.

Edinburgh Nov 6th

#### THERAPEUTIC ABORTION

SIR,—Dr. P. P. Dalton says in his letter (November 5th, p. 849) that "abortion is never justified," so he naturally deplores the term "therapeutic abortion" and he even asks what it means. It surely means abortion performed by a medical practitioner on purely medical—that is, pathological—grounds, the adjective differentiating it from that which is done on other grounds and which is still illegal, except perhaps in cases of pregnancy following rape. To protect family life "is certainly vital and abortion obviously so, where it preserves the health or life of the mother or of a foetus—I am, etc.,

London S.W. Nov 6th

BENJAMIN DUNLOP, M.B., Ch.B.

### Medico-Legal

#### ACTION FOR NEGLIGENCE AGAINST A SURGEON

In the King's Bench Division last week, before the Lord Chief Justice and a special jury, an action was heard in which Miss M. R. Beek claimed from Mr. Neil Sinclair, F.R.C.S., a London surgeon, damages for personal injuries caused by a burn during an operation. The defence was a denial of negligence and Mr. Sinclair counterclaimed £15 5s. as fees for his treatment.

Mr. Malcolm Hilbery, in opening the plaintiff's case, stated that her complaint was that during the performance of an exploratory rectal operation under an anaesthetic the defendant permitted her to be severely burned on the right knee by hot water to which the nurse Miss Verney had left in the bed. Counsel argued that there had been carelessness for which Mr. Sinclair was liable because the surgeon was responsible for the negligence of the person who assisted him at an operation and was under his control.

In her evidence bearing out counsel's opening statement Miss Beek described the after effects of the injury, and how the members of the jury the car on her knee. In cross-examination by Mr. Neilson K.C. she could not recall the nurse having told her that the accident was entirely her fault. Did he not tell you that the burn happened because she forgot to remove the hot water bottle from your bed before the doctor came? No. I cannot remember that. I do not agree with it.

Mr. Cecil Wakeley, F.R.C.S., stated that he examined the plaintiff on November 18th last year—the operation having been performed on March 31st—and found evidence of a burn of the third degree the nerve endings were left exposed in the scar. He agreed in cross-examination that certain duties at operations were usually left to nurses and that while a surgeon performing an examination was in general control he could not be watching for instance the effect of a hot water bottle in the bed.

On behalf of the defendant Mr. Neilson submitted that there was no case to go to a jury but his lordship said he would not stop the case at that stage. Mr. Neilson continuing said that Miss Verney, a highly qualified nurse, was employed by the plaintiff. Before the doctors arrived for the operation Miss Beek asked to keep the hot water bottle which he had in bed with her and Nurse Verney consented meaning to take it out when the anaesthetic was begun. She forgot to do so, however. Neither Mr. Sinclair nor the anaesthetist Dr. Bruce Poole had any idea that the bottle was in bed while the operation was in progress nor had they any reason to think there might be one. The nurse was in no sense the surgeon's servant although it was true that he had power to ask her to do something and if in carrying out such an instruction an accident happened he might be responsible. In this case however the defendant was not responsible for what occurred. So far as those duties were concerned which nurses always carried out a nurse was not the doctor's servant.

Mr. Sinclair in the course of his evidence said it was not until after his examination that he discovered the bottle which was then in the region of the patient's knee. During the operation his attention was directed entirely to what he himself was doing. In cross-examination by Mr. Hilbery he said that the idea that the patient might have a hot water bottle in bed did not occur to him. He took no steps to see if there was one but if he had found one he would have removed it. It was the duty of the nurse to see if such a thing remained in the bed.

Nurse Helen Verney gave evidence hearing out Mr. Neilson's references to her in his opening speech. It had been her intention, she said, to remove the bottle after the patient had settled down but she forgot about it. Mr. Sinclair could not have seen the hot-water bottle unless the bedclothes were turned down. After Miss Beek came round from the anaesthetic she told her that an unfortunate accident had happened for which she, the nurse, was entirely responsible.

Dr. T. Bruce Poole the plaintiff's usual medical attendant who gave the anaesthetic said it was the nurse's duty at an operation to see that the patient was ready for the surgeon in every respect and part of her duty was to attend to the hot water bottles.

Mr. Donald Armour, F.R.C.S., surgeon to the West London Hospital in giving evidence for the defendant described the modern surgical operation as a ritual carried out by a team each member being trained in his or her particular duty. It was the nurse's duty to see to the hot-water bottles in the course of preparing the patient for operation. The modern nurse he added was a highly trained and skilled technician not a surgical twentee. He would not regard it as part of his duty to ask the nurse if there was a hot water bottle in the patient's bed.

Mr. H. S. Soutar, F.R.C.S., surgeon to the London Hospital said that unless there was a separation on the functions of the operator, the anaesthetist and the nurse it would be impossible to carry out modern surgery. It would be most dangerous for the surgeon to let his attention stray to any matter beyond that on which he was immediately engaged. It was one of the nurse's functions to look after the hot water bottles.

#### Judgment for Defendant

The Lord Chief Justice at the conclusion of the evidence for the defendant withdrew the case from the jury and entered judgment for Mr. Sinclair holding that there was no evidence of negligence on the defendant's part to go to the jury. In doing so he said he would say nothing on the question of whether there was any real negligence on the nurse's part. It was easy to be

This book, *John of Gaddenden and the Para Medica*, was published in 1912, a few years after its author's

had obliged him to give up work in a London office and make his home in the country. John of Cadesden, who is depicted therein as the central figure of fourteenth century medicine in England, compiled his famous treatise *Rosa Anglica* or *Rosa Medicinæ* in 1314, and the suggestion has been made that he was perhaps the original of Chaucer's "Doctor of Physic" in the Prologue to the *Canterbury Tales*. In writing about him Cholmeley collected everything from medieval literature that bore on the subject; the book is a storehouse of learning skillfully displayed and a solid contribution to the history of medicine. His many other writings are for the most part scattered anonymously through the volumes of the *Lancet* for the past thirty years, but a few biographies from his pen may be found in the second Supplement to the *Dictionary of National Biography*. Books, flowers, music, and the company of old friends were the things he found best in life, and he had the good fortune to be able to indulge these gentle tastes.

As the editor of the *Lancet* says of him

Cholmeley always described himself as a happy man and the sources of this happiness lay in his own fine character. Much learning left him modest, a truly charitable nature freed him from all bitterness, he had no jealousies and his trained mental qualities gave him the power to enjoy beauty in all forms.

These two sentences touch off the man as we knew him, and it only remains to add a word in friendly recollection of a scholar-physician and a colleague of former days whose passing makes one more blank.

N G H

The sudden death of Dr R. L. ROUTLEDGE of Havdon Bridge is the result of a motor cycle accident while on his rounds, adds another to the long list of tragedies whereby medical men have lost their lives in the pursuit of their avocation. Dr Routledge was born at Rockhope in Weardale just fifty three years ago. He studied medicine at the Newcastle School, and graduated M.B., B.S. in the University of Durham in 1899. For a time he acted as one of the medical officers at the Newcastle Dispensary, and afterwards assisted Dr Gray of Strahope in his homeland. About twenty-three years ago he went to Havdon Bridge, where he took over the practice of the late Dr. Callender. Routledge soon became well known and highly respected in South Tyndale, where his practice included a scattered agricultural district. He was medical officer for the district, and took a great interest in everything which concerned its welfare. He was a strong supporter of outdoor sports, and was actively associated with the Havdon Bridge Cricket Club. He was a member of the Church Council up to about three years ago. In politics he was a Conservative. At the outbreak of the great war he joined the 4th Battalion Northumberland Fusiliers (Territorials), and served throughout. He took a great interest in the local branch of the British Legion. Professor Crev. Turner writes of him "Routledge was always cheery and optimistic, but unassuming and very human, content to minister to his patients and to find recreation in his own home and in promoting the welfare of his own village. He will be greatly missed and mourned far and wide, and not least in many a lonely homestead, for he was kindness itself to his poorer patients. He leaves a widow and one son, who is studying for his father's profession."

By the death of Dr ERIC GEORGE ALEXANDER WEMMES FULTON from lobar pneumonia, at the early age of 27, neurology has lost one of the most promising of its younger followers. The only son of Dr T. Wemmes Fulton, formerly superintendent of scientific investigations under the Fishery Board for Scotland, and lecturer on the scientific study of fishery problems in the University of Aberdeen, Eric Fulton was educated at Aberdeen Grammar School and University, where he graduated M.B. Ch.B. in 1924. He became clinical assistant to the West End Hospital for Diseases of the Nervous System, London, and later held successively the posts of house-physician, resident medical officer and in-patient registrar. In 1926 he was appointed resident

medical officer in charge of the post-encephalitis lethargica unit at the Northern Hospital, Winchmore Hill, of the Metropolitan Asylums Board, under the Ministry of Health, a post which he occupied at the time of his death, at the same time retaining his connexion with the West End Hospital for Nervous Diseases by acting as honorary clinical assistant in the out-patient department. At the West End Hospital Dr Fulton began a series of researches into the comparative diagnostic value of the different physical signs of upper neurone lesions, their significance and their explanation. In collaboration with Dr Woistener Drought, he also investigated in turn every method advocated for the treatment of encephalitis lethargica, both during the acute and the chronic stage. This work extended over several years, and Dr Fulton was still continuing trials of the later methods up to the time of his death. At the Northern Hospital Dr Fulton devoted himself to the study of the problems involved in cases of post-encephalitis lethargica, and some of the results of his observations are embodied in the reports of the Metropolitan Asylums Board, though much of his work, both at this hospital and the West End Hospital, unfortunately remains unpublished. At the time when he was taken ill he was collaborating with Dr S. A. Kinnier Wilson, the consulting neurologist to the Board, in the preparation of a paper on certain post-encephalitic phenomena. His keenness probably brought about his death, since, anxious to complete his investigations, he carried on until he collapsed. One year previously he had an attack of broncho-pneumonia, and for some months had not been in good health, yet he declined to take the rest advised. A colleague writes "Of kind and lovable disposition, Fulton endeared himself to all with whom he came in contact and his loss is sorely felt by patients and professional brethren. Had his life been spared, there is every reason to believe that a brilliant future in neurology lay before him."

Colonel PETER PIERCE M.S. T.A. who died on October 17th, in his 63rd year, received his medical education at Guy's Hospital and obtained the diplomas M.R.C.S. Eng., L.R.C.P. Lond. in 1889. After filling the posts of house-physician and house-physician at Guy's Hospital he was appointed resident house-physician to the Royal Leicester Infirmary. He practised at Tenterden, Kent, for many years, and later in Hove, Sussex, until the outbreak of war. He had always been keenly and actively interested in the Territorial division of the R.A.M.C. He was gazetted lieutenant in 1896, captain in 1899, major in 1907, lieutenant-colonel in 1918, and colonel in 1925. On August 4th, 1914, he was attached to the 5th Buffs, and went out to India in October of that year. In 1915 he served in Arabia with the Aden Field Force, going into action with the Aden Movable Column. He returned to India with the 5th Buffs in 1916, and was invalided home with dysentery. After a few months' sick leave he served first as member and then as president of a travelling medical board. About this time he was awarded the Territorial decoration. In 1918 he was appointed officer in charge of the military hospital at Hounslow, and in 1919 of the military hospital Kingston, returning to the Hounslow military hospital in November, 1919. In January, 1920, he was appointed medical superintendent of the Ministry of Pensions neurological hospital at Shotley Bridge, which post he resigned on being appointed deputy assistant director of medical services to the 42nd (East Lancs) Division for a period of four years. He was later regimental medical officer to the 4th (City of London) Royal Fusiliers from 1923 to 1925, and relinquished this post on his promotion to colonel. He retired, having reached the age limit, on August 4th, 1926. He was engaged in private practice in London up to October 6th last, when he went into a nursing home for a serious operation.

The following well known foreign medical men have recently died: Dr HENRY MEYER of Paris, member of the Académie de Médecine and an eminent paediatrician, aged 64; Dr ALBERT FLORENCE, honorary professor of pharmacology at the Lyons faculty of medicine; Professor MOSELER of Heidelberg, who received the Nobel

prize for physiology in 1910, Dr JOHN GOODRICH CLARK, professor of gynaecology in the University of Pennsylvania, aged 59, Professor RUDOLPH MAGNUS, aged 53, who occupied the chair of pharmacology at Utrecht, and was the author of much valuable work in neurology, Professor KORFF-PETERSEN, director of the Institute of Hygiene at Kiel University, aged 46, Professor PAUL ZWIRGEL, successor of Crede at Leipzig in the chair of gynaecology and obstetrics, Professor NICOLAAS VORHOEVE, who held the chair of roentgenology at Amsterdam, Professor P. KILBURG, a Budapest gynaecologist, Professor ARTURO GUZZONI DEGLI ANGARANI, director of the Obstetrical and Gynaecological Clinic at Modena, aged 69, Dr ERICH MEYER, professor of internal medicine at Gottingen, Dr LOUIS LAURENTIE, professor of obstetrics and gynaecology at Beirut, aged 41, and Professor SACHS, a Vienna dermatologist, aged 56

## Medical Notes in Parliament.

### Parliament Resumes

PARLIAMENT reassembled on November 8th to finish the business of the 1927 session, and is expected to sit till shortly before Christmas. The first business taken was the Landlord and Tenant Bill, followed by the Unemployment Insurance Bill. The Government hopes to pass into law both the Mental Deficiency Bill and the Nursing Homes Bill, though the opposition to the latter may be serious and the time available is scanty.

On November 8th Colonel Lane Fox informed Mr. Lunn that one of the candidates for the new post of medical adviser to the Mines Department had been selected and the usual inquiries by the Civil Service Commission were now proceeding. The name would be announced in about ten days.

On November 8th Sir Kingsley Wood informed Dr. Vernon Davies that the question of the necessity of allowing medical men to preserve professional secrecy in the Law Courts with regard to certain diseases was still under consideration.

On November 8th Sir Kingsley Wood told Mr. H. Williams that 104 schemes dealing with slum areas, covering approximately 14,000 houses, had been confirmed.

## The Services.

### HONORARY SURGEONS TO THE KING

THE following appointments as Honorary Surgeons to the King are announced: Colonel Thomas Kay, D.S.O., T.D., Assistant Director of Medical Services, 52nd (Lowland) Division, Territorial Army, vice Colonel F. H. Westmacott, C.B.E., T.D. (ret.); Colonel Reginald Ernest Bickerton, D.S.O., T.D., Assistant Director of Medical Services, 56th (1st London) Division, Territorial Army, vice Colonel A. D. Sharp, C.B., C.M.G., T.D.

### DEATHS IN THE SERVICES

LIEUT. COLONEL ROBERT WATERS, C.B., of White Fort, Tobermore, county Londonderry, died on August 6th, aged 92. He was born at Tobermore, and educated at Queen's College, Belfast, where he was exhibitioner and senior scholar. He graduated M.D. in the Queen's University, Ireland, in 1858, and took the L.R.C.S. Ed. in 1859. He entered the army as assistant surgeon in January, 1860, was promoted to staff surgeon in November, 1869 (a special promotion for his services in a cholera epidemic at Gambia), attained the rank of brigade surgeon in June, 1885, and retired in April, 1890. He served in the Ashanti war of 1873-74, when he was present at the actions at Amofof and Ordahsu, the destruction of Bequah, and the capture of Kumasi, was mentioned in dispatches in the *London Gazette* of March 6th, 1874, and received the medal with a clasp, and in the Sudan, in the Nile expedition of 1885, first as sanitary officer, later in charge of field hospitals at Korti and Abu Fatma, was mentioned in dispatches in the *London Gazette* of August 25th, 1885, received the medal with clasp, and the Khedive's bronze star, and was promoted specially to brigade surgeon, thus he twice gained steps by special promotion, though he retired, after thirty years, without having attained to administrative rank. In the old regimental days he served in the 21st Foot, the Royal Scots Fusiliers and later was seconded for service in West Africa, where he was principal medical officer of the settlements on that coast in 1873. Towards the end of his service he was principal medical officer of the Quetta district in 1888, and of the Sirhind (Amhala) district in 1889-90. He received the C.B. in 1891, and was a J.P. for county Londonderry.

Lieut. Colonel Henry William Pierpoint, O.B.E., Indian Medical Service, died on July 23th, aged 48. He received his medical education at Liverpool, taking the M.R.C.S. and L.R.C.P. (Lond.) in 1902, and subsequently the F.R.C.S. (1909) and the D.P.H. (Cambridge) in 1911. At Liverpool he took the Gee and H.J. Fellowships, and served as junior demonstrator of anatomy, demonstrator of pathology, and as house surgeon of the Royal Infirmary. He entered the I.M.S. as lieutenant on February 1st, 1906, when he passed in first, he attained the rank of lieutenant-colonel on August 1st, 1925. At the beginning of the war he served on the hospital ship *Syria*, and later in the East, as mentioned in dispatches in the *London Gazette* of June 11th, 1920, and received the O.B.E. on September 9th, 1919. Before the war began in 1914 he served on the Larko Persian Frontier Commission, and after the war was again stationed in Persia as residency surgeon at Bushire. For the last few years, however, he had been superintendent of the Al Ray Institute at Dehra Dun.

## Medical News.

THE Board of Governors has decided that for the future the "Cancer Charity of the Middlesex Hospital" shall be called the "Middlesex Cancer Hospital". The reasons for this change are that the Middlesex Cancer Hospital must be made self-supporting, and, while it will still remain closely associated with the general hospital, it is desirable to recognize the fact that it has become a centre of treatment for cancer patients from the earliest stages of the disease, half the beds are utilized for early cases which will yield to treatment while the other half are still available for cases which, under present conditions, are judged to be incurable.

THE next session of the General Medical Council will commence on Tuesday, November 22nd. The president, Sir Donald MacAlister, Bt., K.C.B., M.D., will take the chair at 2 p.m. and give an address.

THE Huxley Lecture on "Recent advances in science in relation to medicine and surgery" will be delivered by Sir Archibald Garrod, K.C.V.G., M.D., F.R.S., Regius Professor of Medicine in the University of Oxford, on Thursday, November 24th, at 3 p.m., in the outpatients' hall of Charing Cross Hospital.

DR. HENRY DEVINE, O.B.E., will deliver the Longdon Memorial Lecture before the University of Bristol on Tuesday, November 29th, at 8.15 p.m. The subject of the lecture is the reality of delusions.

THE Purvis Oration before the West Kent Medical Chirurgical Society will be given by Mr. Victor Bonney, on Friday, December 9th, the subject being puerperal sepsis.

AT the meeting of the National Institute of Industrial Psychology to be held on Friday, November 25th, at 5.30 p.m., in the Hall of the Royal Society of Arts, 18, John Street, Adelphi, W.C., a number of investigators will describe how psychology enters into the institute's factory investigations. The chair will be taken by the Earl of Balfour, President of the Institute.

AT the annual meeting of the Herefordshire Medical Society, to be held to-day (Saturday, November 12th) at 4.45 p.m., in the Town Hall, Hereford, an address on chronic urinary infection with the *Bacillus coli* will be given by Sir John Thomson Walker. The annual dinner will be held the same evening at 7.30 in the Green Dragon Hotel, Hereford.

THE annual autumn dinner of the Glasgow University Club, London, will be held at the Trocadero, Piccadilly, on Tuesday, November 29th, at 7.15 for 7.30 precisely. Sir Arthur Chamberlain, K.G., the Lord Rector, is to be in the chair, and the Attorney General will be the principal guest. Glasgow University men who, though not members of the club, desire to attend are invited to communicate with the honorary secretaries, 62, Harley House, N.W.1.

THE annual dinner of the London (Royal Free Hospital) School of Medicine for Women will be held at the Grosvenor Hotel, Strand, W.C.2, on Thursday, December 1st. The chair will be taken by Dr. A. G. Phear, C.B., at 7.30 p.m.

THE annual dinner of the Medical Legal Society will be held in the Holborn Restaurant, London, on Friday, December 2nd, at 7.15 p.m., with the President, Sir William Wilcock, in the chair.

THE College of Pestology will hold its annual dinner on November 22nd at the Connaught Rooms, London, under the chairmanship of William Bull, M.P., President of the College, with the President of the College, Sir Alfred Cripps, and Dr. Leonard Hill, F.R.S.

THE Fellowship of Medicine announces that Mr T G Stevens will give a lecture on the treatment of uterine prolapse on November 14th, at 5 p.m. at the Medical Society, 11 Chandos Street. On November 16th Dr S Rodhonso Clovio will give a demonstration at the Victoria Park Hospital for Diseases of the Heart and Lungs, at 10.30 a.m., on the pathology of tuberculosis and there will be a demonstration by Mr Ncume at the Royal London Ophthalmic Hospital, City Road at 1 p.m. On November 17th Mr Herbert J Paterson will give a clinical demonstration in surgery of the London Temperance Hospital, Hampstead Road, at 2 p.m. The lecture and demonstrations are free to medical practitioners. A special course in medicine, surgery and gynaecology begins at the Royal Waterloo Hospital on November 14th and will last for three weeks and occupy the afternoons and some mornings on the same date another course commences at St Peter's Hospital and will continue each afternoon for a fortnight. From November 21st to December 17th the West End Hospital for Nervous Diseases will hold a series of lecture-demonstrations in neurology, at 5 p.m. and from November 28th to December 3rd there will be a post graduate course in proctology at St Mark's Hospital. At the Infants Hospital and at the Blackfriars Hospital for Diseases of the Skin afternoon courses will be held from December 5th and continue to December 17th. Commencing on January 9th there will be a course in medicine surgery and the specialties at the Prince of Wales Hospital and another in diseases of children at the Children's Clinic. These courses will be followed by one in cardiology at the National Hospital for Diseases of the Heart and in psychological medicine at the Bethlem Hospital. Syllabuses and tickets for these courses may be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W 1.

THE third annual dinner of the Isle of Ely Division of the British Medical Association jointly with the Isle of Ely Local Medical and Panel Committees was held at March on October 25th. During the evening Dr G H Stephens was presented on behalf of the practitioners of the area with a gold cigarette case on his retirement from practice and in acknowledgement of his fourteen years continuous chairmanship of the Local Medical and Panel Committees.

AT a meeting of the Central Midwives Board for England and Wales on November 3rd when Sir Francis Champney was in the chair it was decided to inform the London Hospital that the board was unable to accede to the request to suspend in respect of that hospital the rule that the first five patients should be intern cases. It was also resolved that the University of Birmingham having arranged for the holding of the necessary course of lectures to pupil midwives, no other course in Birmingham would be recognized. The board thanked University College, Leicester, for establishing courses of lectures and approved the scheme submitted. The report on the work of the board for the year ending March 31st 1927, was approved and will be transmitted to the Ministry of Health.

AT the twelfth conference of the National Special Schools Union at King George's Hall, Tottenham Court Road, on November 25th and 26th, the subjects to be discussed will include the after care of mentally and physically defective children and mental deficiency in relation to crime and rheumatism. The honorary secretary of the conference is Miss H J Knight, 16c Trinity Square, S E 1.

THE Winifred Munsteron Burke Relief Foundation at White Plains U.S.A., owed its origin to a wealthy founder who desired to relieve worthy men and women in times of sickness or misfortune. Opened in 1915 it has now a city home in New York to deal with the admission of patients and with the assistance to be given to them upon discharge 300 beds at White Plains and one or two smaller institutions for older boys and coloured patients. The patients for whom convalescent treatment was first provided were suffering from heart disorders. Later attention was given to what is called psycho-neurotic or neuro-psychiatric convalescence but the 60,000 patients who have been treated since 1915 include convalescents from many diseases both medical and surgical. The report of the foundation for the two years 1925-27 gives details of the 'reconstructive convalescent regimen' the 'occupational therapies graded into wage work' and the 'play care and psychotherapies' which are carried on in the buildings and their sixty acres of grounds. The length of stay of the patients varies from days to months with an average of three or four weeks. An interesting experiment has been tried in throwing open athletic fields and lawns to school and community recreations. This entitles the patients and incites them to be in milder forms of exercises. As the daily cost of each patient including transportation and the admission department is less than two dollars it would appear that the administration is economically conducted.

DR GRAHAM LITTLE M.P. for Lough University, has been elected an Honorary Member of the Royal Academy of Medicine of Rome, and a Fellow of the Royal Society of Physicians of Budapest.

LOUGHBOROUGH COLLEGE, Leicestershire, England, invites applications for the award of five open scholarships in the faculty of engineering, each of the value of £75 a year. The scholarships are open to all British subjects resident in any part of the Empire and are tenable at Loughborough College for the period of the full diploma course. Candidates must be not less than 16 years of age on October 1st 1928. Further particulars and forms of application (which must be returned not later than April 1st, 1928) may be obtained from the college registrar.

DR G N HENRY, divisional surgeon to the L Division (Lambeth) Metropolitan Police, has retired after thirty six years service with the Force.

WE have received the first issue of a monthly journal entitled *Revista de neuro oftalmologica y de cirugía neurológica* which was published in July at Buenos Aires under the editorship of Drs J Lijo Pavari and Dr Poque Orlando. The issue contains original articles on the photography of the fundus oculi, by Dr Pavio hemiplegia in flexion, by Dr J M Obarrío a post-encephalic syndrome by Drs M R Caster, A F Camner, and A Battro and circumscribed labyrinthitis by Drs J Bosavilhao and D Sibald abstracts from otolaryngological neurological and ophthalmological literature, and society intelligence.

PROFESSOR AUGUSTO METTI of Bologna, who has recently reached his 86th year, has presented sets of thirty six medical periodicals, including the BRITISH MEDICAL JOURNAL and the *Proceedings of the Royal Society of Medicine*, to the Medico-Chirurgical Society of Bologna.

THE fourth Brazilian Congress of Hygiene will be held at San Salvador in December when the subjects for discussion will include the epidemiology and prophylaxis of plague, domestic insects, biometry of children and adults, water supply, and prophylaxis of spirochaetosis.

PROFESSOR KERL of Innsbruck has been nominated director of the clinic of venereal diseases at Vienna in succession to Professor Finger.

PROFESSOR PAUL LECÉF, who occupies the chair of surgical pathology in the Paris Faculty of Medicine, has been nominated an officer of the Legion of Honour.

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring PEPPINTS of their articles published in the BRITISH MEDICAL JOURNAL must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the JOURNAL should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the BRITISH MEDICAL JOURNAL are JULY 5551 5552 5553 and 5554 (internal exchange four lines).

THE TELEGRAPHIC ADDRESSES are  
EDITOR of the BRITISH MEDICAL JOURNAL *Antology Westcott London*

FINANCIAL SECRETARY AND BUSINESS MANAGER  
(Advertisements etc.) *Antology Westcott London*

MEDICAL SECRETARY *Mediscera Westcott London*

The address of the Irish Office of the British Medical Association is 46 South Frederick Street Dublin (telegrams *Brillux Dublin* telephone 4137 Dublin) and of the Scottish Office, 6 Drumshough Garden Edinburgh (telegrams *Scotat Edinburgh* telephone 2 351 Edinburgh).

## QUERIES AND ANSWERS

INTRAVENOUS asks for suggestions as to the best way of keeping syringes and needles so that they may be ready for immediate use without continue sterilization by boiling.

W G who suffers from coldness of the hand which is not prevented by ordinary fur lined gloves asks to be recommended some kind of gloves or other device which will meet his difficulty.

## STAMMERING

"H. L. E." asks for references to literature and suggestions as to home treatment of a boy of 14, who began to stammer at the age of 6, probably as the result of a long illness and an operation; he is left-handed in writing. His mother was a stammerer in childhood, but has outgrown the defect.

## STOMACH COUGH

Dr A. S. McNEIL (Liverpool) writes to suggest to "M. B. Cantab" that the symptoms from which he desires relief are probably due to abdominal visceroptosis, the "status" of which he complains being gases given off into the stomach and intestines by the blood vessels when, owing to the recumbent position of the body, they are allowed temporarily to resume an approximately correct anatomical position. The cough, of course, is reflex vagal in character. It would be wise, no doubt, to verify the position by a complete x-ray examination of the stomach and intestines, and if visceroptosis is shown to be present, a suitable abdominal support worn in the daytime would, I think, relieve. A little gentle exercise of the abdominal muscles, each night and morning, would also be advisable.

## PREVENTION OF SCABIES

A WOMAN member of the profession who contracted scabies over a year ago has three times got rid of it, but on each occasion has been reinfected after varying periods. This she attributes to wearing some article of clothing which has not been thoroughly disinfected. Women's clothing being what it is, she asks what is the best disinfectant for garments which cannot be boiled.

## GLOSSITIS

"G. O." asks for suggestions for the treatment of a woman, aged 30, who has an enlarged tongue, with fissures and patches of desquamation. It is intensely irritating and uncomfortable. The usual methods of treatment have been tried, as well as dental, gastric, and tonsillar treatment, and x-rays, without effect.

## INCOME TAX

## Partnership Assessment

"R. O." took over a practice from August 1st, 1924. His predecessor's figures were unknown and he paid tax for the period to April 5th 1927, on the basis of the amount of his earnings, as shown by accounts prepared for each of the two years to August 1st, 1926. He has been assessed for 1927-28 on £515 the amount of profits for the previous year—that is, to August, 1926. He has now been asked for a copy of his accounts to August, 1927. Has the Inspector any right to alter the 1927-28 assessment if the result of these accounts should show an improvement on the previous year's figures?

\* \* No, probably there is no intention to do so, but perhaps the local office is desirous of getting forward with next year's work—that seems the only explanation of the request.

## Expenses of Employment

"A. D. K." obtained an appointment as from May 1st, 1927. He found it necessary to purchase a car for £160, and receives an allowance for its use at 6d a mile. He calculates that the cost of the car, inclusive of depreciation, exceeds the mileage allowance. He asks whether he can claim to deduct anything in respect of the purchase of the car or the excess annual cost.

\* \* The purchase of the car represented capital outlay, and no allowance is due for that expense. On general principles "A. D. K." is entitled to deduct all expenses incurred solely, exclusively, and necessarily in the performance of his duties, but we think he will find it very difficult to convince the Commissioners that the county council allowance of 6d a mile is inadequate to cover all necessary costs of travelling—for example, is the car of the minimum horse power necessary for his work—and if that is so, it is useless to appeal.

## Locumtenent's Expenses

"Loco" has been taking locum work for the past few years through an agent, to whom he pays a commission of 1s for each £1 he earned. The income tax authorities have refused to allow him to deduct the commission as an expense.

\* \* Apparently, "Loco" is being assessed under Schedule E as for the profits of "employment" and it is agreed that the expense of obtaining employment is not deductible under the rules of Schedule E. We suggest that the basis of the assessment is wrong and that our correspondent should be assessed not as an employee, but as a man practising his profession in a special way. As such he would be assessable under Schedule D for the profits of his practice and in such a case the commission payable year by year would properly be deductible. If Schedule E is the correct basis of assessment it would seem that separate assessments should be made for each separate "employment," which presumably has not been done.

## Deduction for Use of Car

"D. M. M." states that the inspector of taxes declines to allow him to deduct the expense of using his car for travelling to the station to take trains on professional visits.

\* \* We can see no justification for the distinction. The professional journey starts from the professional headquarters—the surgery or consulting room—and the expense covers the whole journey out and back.

## LETTERS, NOTES, ETC.

## DISEMBOWELMENT AND SHOCK

Dr E. W. GOODALL (Hemlingford Abbots Hunt) writes in connexion with this subject (November 5th, p. 847) the following quotation may also be of interest. It is taken from chapter vii, Lane's *Manners and Customs of the Modern Egyptians*, which was first published in 1835. The writer is giving instances of extraordinary feats performed, for the purpose of reward, by the processions of the brides of wealthy families.

When the Seyid Omar married a daughter about twenty-seven years since there walked before the procession a person who had made an incision in his abdomen and drawn out a portion of his intestines which he carried before him on a silver tray. After the procession he restored them to their proper place and remained in bed many days before he recovered from the effects of this foolish and disgusting act.

Lane states that this incident was described to him by an eye-witness. But was the latter pulling the former's leg?

## CONSTIPATION IN INFANCY

Dr W. J. BURNS SELKIRK (Edinburgh, Birmingham) writes: When is a baby genuinely constipated? When rectal examination of the little finger determines the presence of a mass of faeces which the baby cannot pass? The rectum of the constipated is often empty. If when a baby defecates, the mellow is soft there has not been constipation. Under feeding or perfect digestion may only give one action in forty-eight hours. Even at some welfare centres syrup of figs is unjustly advised the natural reflex thereby impaired, and a drug-taking child and adult likely to result—then justifiably labelled 'constipated'. Most "constipated" babies are not constipated till submitted to human interference.

## TREATMENT OF VARICOSE VEINS BY INJECTION

Dr T. O. GREENE (American Presbyterian Mission, Peking) writes to call attention to a case of death following injection for varicose veins recorded by Dr O. A. Olson in the *Journal of the American Medical Association* (August 27th, 1927, p. 63). Dr Greene writes: A woman of 33 developed varicose veins during her first pregnancy. Two children, the youngest aged 2, were living and well. In 1924 she aborted in the second month. The Wassermann reaction was negative. No rupture of the veins occurred, and she was treated with elastic stockings until June 1927. So we have a typical uncomplicated case of varicose veins of several years' duration. On June 3rd and June 8th she received injections of salt solution and caloric. "She felt perfectly well until June 13th, when at 5 p.m. while playing with her children, she felt dead." Autopsy showed (1) varicose veins, (2) phlebitis and thrombosis of the right internal saphenous vein, the thrombus exhibiting a broken off end. (3) pulmonary embolism. It may be advanced that another solution would have given a happier result. If the rationale of this treatment is to produce a sterile phlebitis and consequent thrombosis, the underlying principle would seem dangerous, no matter what the agent used. To produce a thrombus or to risk producing a thrombus, in a vessel in which the current is directed towards the heart, and whose calibre increases in the direction of flow, would seem hazardous at least. The current in a varicose vein may at times be away from the heart, or stationary, but certainly it often is directed towards the heart. In the aetiological and surgical treatment of varicose veins there is the risk of embolism from the thrombus which would extend proximally from the highest point of venous ligation. A priori, this risk would be less than the risk of embolism following the injection of varicose veins.

PULMONARY MEDICATION BY RIGHT CARDIAC INJECTION. THE Academy of Medicine in Paris lately heard a paper by Drs Cherechewski, Florentin, and Desboursyres suggesting the injections into the right side of the heart might be used in the treatment of affections of the lung. Being dissatisfied with the results of attempts at disinfection of the lungs by repeated administration by the mouth by inhalation and by intratracheal injections, and finding intravenous injections difficult, the authors decided to try puncture of the right side of the heart as the surest point of access to the lung. They found that dogs tolerated very well an injection of 1 per cent solution of methylene blue and that at the end of ten minutes the lungs had taken on a grey colour with scattered blue points. In less than half an hour the colouring substance was distributed evenly throughout the lung tissue. The method was tested in a dog suffering from distemper, a solution of "collibacterin" (1 per cent) with methylene blue was injected into its heart for several consecutive days. The treatment was followed by marked amelioration of the general condition but did not bring about a cure. The authors think that the injections might be tried in pneumonia in man or animals when all other remedies have failed and for pulmonary tuberculosis in man.

## VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments are to be found at pages 36, 37, 33, 39, 42, and 44 of our columns and advertisements as to partnerships and other vacancies at pages 40 and 41. A short summary of vacant posts notified in the *British Medical Journal* appears in the Supplement at page 123.

## THE PRESENT POSITION OF KNOWLEDGE

AS TO

## PROSTATIC ENLARGEMENT

*Being the Bradshaw Lecture delivered on November 10th,  
1927, to the Royal College of Surgeons of England,*

BY

SIR CUTHBERT WALLACE, KCMC, CB, FRCS,  
SURGEON TO ST THOMAS'S HOSPITAL.\*

## FUNCTION AND FORM

RECENT years have added little to our knowledge of the function of the prostate. It is not apparent that it has any internal secretion, or that it exercises any influence on metabolism, it is a secondary sexual gland.

The glands that make up the prostate spring apparently from all sides of the urethra but the anterior group ultimately atrophy. The gland mass that lies below the ejaculatory ducts is seldom the seat of changes and usually retains its spongy nature.

Long before birth the prostate has assumed its adult form and the gland tubules the distribution that persists throughout life. There is no indication of any division into lobes or lobules. The tubules run out from the side or posterior walls of the urethra, tending to bend forward as the distance from the urethra increases. In front there is very little if any gland matter. This glandless area represents an atrophy of tubules, not a fusion of constituent lobules. None of the tubules of the gland reach the surface thus leaving another non-glandular portion. Lastly, there is always a considerable thickness of non-glandular tissue surrounding the urethral canal.

## HISTORICAL

[The history of prostatectomy was then reviewed, beginning with the early work of McGill of Leeds (1887).]

From 1880 until the close of the century the operative treatment of enlarged prostate was undergoing a slow and painful evolution. In 1888 Harrison of Liverpool was advocating perineal section and prostatectomy, more especially in those cases of foul urine and degenerated kidneys and in this way seems to have laid the foundation of the present two-stage operation, but the general feeling of the profession can be gauged by the eagerness with which the so-called sexual operations were taken up. In the late nineties the operation of prostatectomy was again making headway, and the sexual operations having been found wanting were declining. In 1900, while the treatment of enlarged prostate was still chaotic, Freyer published his series of successful cases, which anyhow in this country, re-established prostatectomy as an operation of choice.

Since this time the suprapubic operation has found favour with most surgeons, and the technique of its performance has remained in the main unaltered. The perineal operation has, however, found some formidable advocates, and appears at the present time to be gaining ground.

## THE SEXUAL OPERATIONS

In 1775 John Hunter made the classical observation on the want of development of the prostate that resulted from castration in youth or infancy. Castration as a remedy for prostatic enlargement was suggested to White of Philadelphia by the shrinking of uterine fibroids after ovariectomy, the uterus being considered a homologue of the prostate. It was found by experiment that castration of adult dogs was quickly followed by atrophy of the prostate. In 1889 Griffiths had reported to the same effect.

Treatment by castration, although put forward as a

The report has been slightly abridged by the omission of some introductory matter.

demeically, was taken up with a rush, and, like many new treatments, was at first apparently efficacious. Even unilateral orchiectomy was reported to be efficient. The literature of the period, however, shows that castration could not be relied upon to cause an atrophy of the enlarged prostate.

Vasectomy was next proposed as a slighter operation, but one warranted to produce the same effect. It had a vogue, but gradually it also lost favour, and with it the sexual operations ended. Mr Shattock and I did some experiments to test this matter. We found that, while cutting off the blood supply caused an atrophy of the testicle, division of the duct left the testicle entirely intact. While in the midst of these experiments we discovered that John Hunter had made the observation in the human subject that the testicle developed and contained spermatozoa although there was no connexion between the testicle and its excretory canal. In vasectomy, as practised for the relief of prostatic enlargement, we have an example of how careful one must be to verify the facts before applying them.

## CAUSATION AND NATURE OF THE ENLARGEMENT

Two theories as to the nature of prostatic enlargement have alternately held the premier place—the infective and neoplastic. Nothing of interest in this connexion has come to light of recent years, except that Hugh Young by a careful statistical inquiry, has shown that gonorrhoea at all events, plays no part in the etiology. At present most people regard the enlargement as due to the growth of adenoma, and if this is accepted the cause of prostatic enlargement is the same as that of other such growths. In this association it may be useful briefly to allude to certain facts.

- 1 The growths reproduce fairly faithfully the histological features of the parent both as regards stroma and gland tissue.
- 2 Encapsulation is usually very complete especially in old standing case.
- 3 Sometimes however the encapsulation is incomplete and recalls certain adenomata of the breast.
- 4 The growths are often compound one adenoma comprising several small ones.
- 5 The time of appearance is late in life and this may have some connexion with the proclivity of the growths to become carcinomatous.

## POINT OF ORIGIN OF THE ADENOMATA

There is still some difference of opinion as to the exact place in the gland at which these masses arise. One school maintains that they are not true prostatic tumours, but arise in the subcervical glands or in those of Albarran, both of which are submucous, in far the greater number of cases however, the point of origin lies well within the prostate proper. The adenomatous masses usually arise in connexion with the acini which enter the prostatic urethra above the mouth of the ejaculatory ducts that portion of the gland which lies below seems little prone to this change and often retains its normal spongy texture after the rest has undergone a complete change.

## CAUSATION OF SYMPTOMS

The symptoms which must be of local origin since bladder function returns practically to normal when the obstruction has been removed, may now be discussed.

Frequent and precipitate micturition may be explained by thinning and then replacement of the contractile tissue about the internal meatus by the adenomatous growth.

Hesitant and interrupted micturition are more difficult of explanation. Hitherto they have been put down to the ball-valve action of the "third lobe." Now a growth behind the urethra that could act in this way is a rarity, and I would suggest that these symptoms are caused somewhat in the following way. The urethra is surrounded by an adenomatous mass which is under tension caused by its growth stretching the pathological capsule. The urethra is also bent at an angle so that it forms a kind of flap valve. For urine to pass, the pressure in the bladder has to be so adjusted that it can overcome the increased pressure within the urethra and at the same time be insufficient to shut the valve. Any departure from the

optimum bladder pressure will cause a cessation of the flow of urine. The distressing symptom of dribbling from the urethra after the act of micturition should have been finished may be accounted for by the elongation, stretching, and distortion of the canal by the adenomata which have replaced the normal contractile tissue or hindered its orderly action.

*Residual urine* is the most difficult symptom to explain—in fact, it never has been explained. The most ingenious solution is that which attributes it to the intravesical pressure on the varying cone-like projection of the prostate into the bladder. When the bladder is full the cone will project but little, but as the organ empties the cone will offer a greater surface that is subject to pressure, with the result that the urethra becomes occluded. Unfortunately for this explanation a vesical cone is not always present.

I would suggest that residual urine is really a case of bladder posttome. Fullness of the bladder is a relative term. The usual act of micturition, when once the initial stimulus of distension has been given, is continuous. The bladder during the process of emptying will contain from time to time an amount of urine which in process of filling had produced no desire for micturition. If the act of emptying is slow or interrupted, as it is in prostatic trouble, it is possible to imagine that the impulse necessary to carry the act to completion becomes dormant or fails to be again initiated, to speak in homely terms, the bladder imagines itself to be empty.

#### THE FATE OF THE CAVITY LEFT BY OPERATION

Even before the revival of prostatectomy it was asserted that the procedure consisted in the total removal of the prostate. This was given as an explanation of the success of the operation. It is, however, now, I think, generally admitted that the modern operation for prostatic hypertrophy consists in enucleation of adenomatous masses from within the expanded outer portion of the organ, and that there is no real solution of continuity between the bladder and the urethra. That fact accounts in part for the almost unbelievable fact that the operation is very seldom followed by stricture.

After the enucleation the urethra and bladder are joined by a ragged cavity, which may be at that moment of very considerable dimensions. Very soon after the removal of the adenomata, or rather at the very moment of their removal, the cavity contracts centripetally, so that not only are the sides of the cavity approximated, but the bladder is at the same time approximated to the urethra. This contraction is brought about by the resilience of the remaining part of the prostate, and it may be remembered that it is this resilience pressing on the central adenomatous mass which is in part the cause of the urinary difficulties. This contraction at the time of operation is a very real thing, and gives rise to considerable difficulty if the surgeon wishes usually to explore the cavity. After the operation the cavity continues to retract, so that in some cases within a few weeks a skigram of the bladder shows no sign of its existence. Sometimes, however, a distinct cavity remains for a considerable period, though micturition is perfectly normal. It might be urged that the existence of this cavity shows that the internal sphincter is out of action. There is, however, another explanation—it is possible that, in those cases in which a cavity persists, the growth has been largely intravesical, and that the top of the cavity corresponds, not to the internal sphincter, but to the level to which the mucous membrane of the bladder has been raised.

When an opportunity occurs of inspecting and digitally examining a bladder after prostatectomy, it is remarkable how little abnormality is to be made out, perhaps there is a small dimple at the internal meatus, or the meatus is not so dilatible as it normally is, and reminds one of the state of affairs in encystoma or in the so-called "Meisner's bru." Again, it is almost impossible to be sure by rectal examination whether the prostate has been removed or not.

The two-stage operation was introduced quite early in the history of prostatectomy to rest the patient who was worn down by sepsis and want of sleep. The indications

for its performance were at first almost entirely empirical. The discovery and perfection of tests of urinary efficiency have extended and rendered more accurate the indications for the performance of this operation.

It entails, however, certain disadvantages. The first is that there are two anesthetic administrations and two periods of anxiety and discomfort. The second is that the enucleation is made more difficult by the shrinking of the bladder, the hardening and contraction of the prostate, and the induration of the abdominal wall. In addition, the wound may become foul and phosphatic deposit give trouble.

If the two stage operation is decided upon, the relative merits of catheter and suprapubic drainage are to be considered. The catheter has been with many surgeons very successful, it avoids two operations, but it may give rise to a urethritis which is troublesome, and in some cases to a definite rise in the blood urea. Suprapubic cystostomy has the great advantage that the condition of the prostate can be accurately determined by the only certain means—namely, that of bimanual examination.

I have nothing to say about after treatment, except to express the opinion that, whatever is the means favoured to carry off the urine after prostatectomy, the less the prostatic couch is interfered with the better. I have been very free from secondary haemorrhage, and I attribute this to only washing the bladder out in exceptional circumstances.

#### URINARY EFFICIENCY

There are, of course, discrepancies between the various tests or parts of the same test, but in the main a fairly just estimate as to the efficiency of the kidneys can be formed.

Mention must here be made of what is, to me at all events, a difficult problem. When is the surgeon justified in refusing to proceed to a second stage prostatectomy? There are a certain number of patients on whom a drainage cystostomy has been performed, and whose urinary efficiency, as judged by the usual tests, has never fallen to a figure that would, in the first instance, have warranted a single stage prostatectomy, although in other ways they seem to be in good health.

The question to be decided is this: What percentage of urinary efficiency is to be taken as justifying completion of the operation after a period of drainage?

The mechanism whereby the loss of efficiency of the kidney is brought about is still unsolved. It is doubtful what effect the obstruction to outflow has on the constituents of the urine and what is the ultimate fate of a kidney whose duct has been completely occluded for varying periods.

The rapid improvement that takes place in some cases after drainage of the bladder is mysterious. Perhaps the easiest explanation is that which attributes recovery of drainage to vascular compression and not to histological change.

#### BACK PRESSURE

It is usual to attribute the troubles of the kidney simply to "back pressure," but when the subject is examined more carefully it is not so easy to understand how the kidney is subjected to an obstruction lasting over a long period. It is not very obvious why we speak of back pressure in connection with the kidney and do not use the term when we talk of obstruction in connection with other ducts and the intestinal tube. It is an unfortunate expression, because it sometimes leads to the belief that the pressure which injures the kidney originates in the bladder as the result of tension or of muscular contraction.

The pressure that dilates the ureter and distends the kidney is the secretion pressure of the kidney, and it is of interest to consider what are the pressures in the bladder that hinder the ureter in propelling the urine into the bladder, so long as the meter can get rid of the urine, the kidney will be shielded from any noxious pressure.

I am indebted to Mr. B. W. Williams for the observations incorporated in Table I. These show the pressures in the bladder of some cases of retention. The pressures, by means of a water gauge and have been reduced to

metics of mercury, as more readily appreciable. The pressures recorded are those found in the intervals between spasms of the bladder.

TABLE I—Pressure in Bladder in Cases of Retention

Case No.	Duration of Retention	Bladder Pressure in mm. Mercury	Amount of Urine	Case No.	Duration of Retention	Bladder Pressure in mm. Mercury	Amount of Urine
1	36 hrs.	8-10	35 oz.	6	12 hrs.	34	46 oz.
2	7 days	2-25	85 oz.	7	24 hr.	27	50 oz.
3	48 hrs.	22-25	45 oz.	8	24 hrs.	15	50 oz.
4	overflow	19	29 oz.	9	22 hrs.	8-10	30 oz.
5	3 days	29	47 oz.	10	24 hrs.	24	40 oz.

It will be seen that the maximum pressure which the ureter has to overcome in a case of acute retention of urine is about 34 mm. of mercury. The pain occasioned at such a pressure is not to be endured; the individual is compelled to seek relief. From this it appears that any high pressure that may act injuriously on the kidney must be of very short duration.

In most patients even in those with a considerable amount of residual urine the pressure against which the ureter has to work must be very slight. In fact, it is difficult to see that the pressure in the bladder in most cases of residual urine can be greater than that which pertains in the ordinary course of filling of the bladder. It follows that there are three possibilities, which are: (1) that the kidney is extremely sensitive to any obstruction or (2) that the damage done is in the nature of a sudden catastrophe (during an attack of retention) or (3) that we must seek some unknown cause of kidney deterioration.

#### THE SUPRAPUBIC AND PERINEAL OPERATIONS COMPARED

While the suprapubic method of operating has been chosen by the great majority of surgeons, the perineal has been practised by surgeons of great repute and experience, one of whom has probably the lowest mortality of anyone. It is therefore useful to inquire whether there is any reason for the majority to change their methods. It is claimed that (1) the perineal is the more scientific, in that the enucleation is more deliberate and is performed under the eye; (2) the ejaculatory ducts can be saved or ligated; (3) the urethral wall can be left intact and (4) the loss of blood is less.

To take these points one by one:

1. Some surgeons might say that by using a large vesical incision the enucleation can be carried out as openly and as deliberately by the suprapubic as by the perineal route. Putting this contention aside for the moment it may be considered whether the enucleation under the eye is a material advantage. Removal of the adenomata is not a matter of delicate and difficult dissection but really consists in entering a line of cleavage already established and following it to its end. It therefore matters little whether this is done under the eye or not. An accurate judgement that all adenomata have been removed can be formed by bimanual examination when the suprapubic route has been used.

2. As regards the preservation of the ejaculatory ducts, if it could be shown that children had been born to patients who had undergone perineal prostatectomy it would be a point in favour of that operation as a restoration *ad integrum* is always desirable. I am unaware, however, that a man has ever begotten a child after a prostatectomy. As regards a man's virility apart from power of procreation we have already seen that section of the vas produces no effect. It is not very clear whether the occurrence of epididymitis is caused or prevented by rupture of the vas. If opening the canal can cause an infection to spread to the epididymis, it cannot be denied that infection can occur with an intact vas or one in which the lumen has been obliterated by ligature after rupture. In the matter of the vasa, therefore, it does not seem that

the perineal method has any advantage over the suprapubic operation.

3. My observations on many *post-mortem* and operative specimens have led me to doubt the possibility of leaving the urethral wall intact in any but a very small and insignificant number of cases and I should not be influenced on this account in the choice of the operative route.

4. If excessive bleeding could be certainly and effectively diminished by the perineal route that would be a very good argument in favour of its adoption.

5. As regards restoration of function, and absence of a perineal operative sinus the suprapubic method leaves little to be desired.

Professor Hans Wildholz, in a recent communication, has advocated the use of the perineal method and the suture of the neck of the bladder and the distal portion of the prostatic urethra. He also states that the mortality of the operation is less than that of the suprapubic method, that the former method leads to a smaller rise in the blood urea that sepsis is practically abolished and that union takes place *per primam*. If other surgeons can reach the same results it will be a great argument in favour of the perineal method.

#### BEST TIME FOR OPERATION

It is fortunate that although the adenomata may be multiple, they are usually all of an age so that when they have necessitated operation their removal is not followed by the formation of others. It should be the aim of the surgeon to remove the obstruction before the urinary function is depressed.

If the prostate is large and resilient and the life of the patient is disturbed by his trouble the decision to operate presents no difficulties. On the other hand if the prostate presents no great departure from the normal and the patient is willing to put up with what discomfort he has most surgeons would, I think, be willing to wait, provided the kidneys are efficient and the patient can be watched.

More difficult are those cases in which the life of the patient is being somewhat disturbed by urinary troubles and examination by the rectum reveals a prostate perhaps a little large but not much altered in shape or size. Such a case may prove to be one of simple prostate which has not greatly enlarged or not enlarged toward the rectum, a case of carcinoma, or 'prostatic bar'. I know of no sure way in which the matter can be settled except by opening the bladder and bimanual palpation.

It has been truly said that if an individual is destined to have trouble with his prostate he is lucky if the organ, so to speak, ripens quickly about the age of 60. The kidneys will most probably be in good condition; a single-stage operation is possible, and there is a prospect of many years of health and enjoyment of life.

#### CARCINOMA

Hitherto the treatment of carcinoma has not been satisfactory either from the operative or radiation point of view.

Operative treatment involves the entire removal of the gland. This is a difficult and tedious procedure. It has been accomplished however in a limited number of cases by the perineal and by the transpubic routes and the feasibility of a satisfactory union of the bladder and urethra demonstrated. If the mechanical difficulties of removal have been got over it cannot be said that the difficulties of diagnosis sufficiently early to justify a serious operation, and offer a reasonable prospect of cure have been surmounted. Herein to my mind, lies the crux of the question. The diagnosis of carcinoma is usually made on the hardness, the nodularity, the fixation of the prostate as felt per rectum and the inelasticity of the internal meatus as felt from the bladder. By the time that the signs of malignant disease are irrefutable, as judged by a rectal or cystoscopic examination, the time of successful intervention is probably past. The rigidity of the internal meatus, which is a useful sign, can only be ascertained after a suprapubic cystostomy; this is a distinct advantage if the prostate is to be excised by the perineal route.

Again, there is the difficulty of diagnosing carcinoma from that undifferentiated group of affections that may be classed under the term "post-urethral bar."

Adeno-carcinoma in its own way presents almost as great a difficulty. This condition may be diagnosed in the process of enucleation of a presumed adenomatous mass, or it may not be diagnosed until after a microscopical examination.

Here the surgeon has three courses open to him: (1) He can proceed forthwith to total extirpation of the prostate, removal of which will have been made all the more difficult by the already accomplished operation. (2) He can wait and put the matter before his patient. (3) He can allow the bladder to close, if it will, and establish a suprapubic drain when obstruction supervenes, which usually happens within six months.

#### RADIATION

Radiation has been carried out from the urethra, from the rectum, and by means of needles introduced through the perineum or through the bladder; deep therapy has also been used.

Radiation in carcinoma of the prostate is in the same condition as radiation for carcinoma in other parts of the body. We are slowly and painfully groping our way towards a better knowledge. There are many groups of observers doing good and careful work throughout the country, but I cannot help wishing that someone who has the means would by his generosity render possible a more intensive study of the subject.

Professor Sidney Russ of the Middlesex Hospital has kindly prepared for me the accompanying table of the radium publicly owned in the countries named. The figures for the British Isles include the radium held by the London, Manchester, and Glasgow institutes.

TABLE II—Estimates of Radium Publicly Owned (1927) for Medical Purposes

Country	Population (Millions)	Grams of Radium	Grams per Million
Australia	6.2	10	1.60
Denmark	3.3	2	0.59
Belgium	7.5	4	0.53
France	40	18	0.45
British Isles	45	11.5	0.25
Sweden	5.5	1	0.18
Germany	56	2	0.04

#### MORTALITY

It is extremely difficult to arrive at a just estimate of the mortality of any operative measure. It is almost always better in private practice than in hospital, owing to the different social classes from which the patients are taken.

I may give, in the first place, a few instances of figures given by individuals. In 1893 White of Philadelphia gave the mortality of the perineal route as between 13 and 14 per cent, and that of the suprapubic as 20 to 25 per cent. In 1912 Fiebert gave the mortality in 1,000 cases as 5½ per cent, and stated that in the last 100 cases it had fallen to 3 per cent. Hey Grove, commenting on these figures, said that he had taken the mortality for all the available large hospitals in the kingdom and found it to be 40 per cent. Hugh Lett in 1913 said he believed that the mortality of hospital patients was 20 per cent. Fullerton stated in the same year that his mortality in 55 cases was 7.2 per cent.

Hugh Young, in his *Practice of Urology* (1927), gives his mortality for the perineal operation as 3.4 per cent in 1,049 cases, and Wildbolz just recently has stated that his mortality for the suprapubic method (105 cases) is 15 per cent, and for the perineal operation (305 cases) is 6.5 per cent. These figures show very real differences.

Through the courtesy of some surgeons I am able to show some figures from different London hospitals, which are a good guide, as showing the results in one class of patients.

TABLE III—Statistics of Prostatic Enlargement and Prostatectomy from Four London Hospitals  
(The figures are the last available)

	Total	Died	Mortality	Individual Mortality
Enlarged prostate	831	131	15.8	13.1—13.5—17.8—22.1
Prostatectomy	621	88	14.2	12.9—14.5—17.5—20.8

An absolute mortality has a definite value, but a more satisfactory way is to contrast two sets of comparable statistics. Thus I can fortunately do Mr. Max Page, in the *St. Thomas's Hospital Reports* for 1910, published the results of prostatectomy at St. Thomas's Hospital, and these can be compared with more recent figures (see Table IV).

It is at once apparent that the mortality from prostatic trouble has not materially fallen, that of prostatectomy has fallen from 20.2 per cent to 14.5 per cent, but the total operative mortality has somewhat risen.

It will be seen that the surgeon has been more chary in performing the one-stage operation, and that the deaths that formerly would have been recorded under prostatectomy are now found under cystostomy. If hospital statistics are to be improved the patients must seek help earlier than hitherto.

A striking fact is the good results that follow the two-stage operation, in spite of certain disadvantages.

In conclusion, I think one may say that, whatever is the true mortality of prostatic enlargement, the outlook for the prostatic patient has improved out of recognition since 1886.

TABLE IV—Simple Enlarged Prostate

Treatment	1905-1910 Total Cases 131 Died 23				1922-1925 Total Cases 219 Died 44					
	Suprapubic Prostatectomy		Suprapubic Cystostomy		Suprapubic Cystostomy		Suprapubic Prostatectomy		Total	
	Total	Died	Total	Died	Total	Died	Total	Died	Total	Died
	69	14	20	4	41	21	77	9	63	12
Method mortality	20.2		20.0		51.2		11.7		17.6	
Prostatectomy mortality	20.2								14.5	
Total operative mortality			20.2				22.5			
Total mortality			21.7				22.1			

# THE ADMINISTRATION AND THERAPEUTIC USLS OF OXYGEN

## I—OXYGEN ADMINISTRATION\*

BY

H. WHITRIDGE DAVIES, M.B., B.S. ADELAIDE

Lecturer in Physiology and Pharmacology in the University of  
Leed

THE first consideration with regard to oxygen administration is the object to be attained. Oxygen administration is necessary in any circumstances where the tissues are labouring under the disadvantage of oxygen lack. Following the classification of Barcroft† we may divide these conditions into three types. In the first of these anoxic oxygen lack, owing to alteration in the atmospheric environment or to impairment of the gaseous exchanges in the lungs, the arterial blood does not contain its normal amount of oxygen. In the second, the anæmic type of oxygen lack, owing to deficiency or alteration of the hæmoglobin, the blood is unable to carry the oxygen which is presented to it in the pulmonary alveoli. In the third or stagnant type of oxygen lack the arterial blood contains its normal amount of oxygen but, owing to local or general circulatory causes, an insufficient amount of blood reaches the tissues which are therefore deprived of oxygen. The untoward effects of all these three conditions can be overcome, more or less completely, by the administration of oxygen, but the amount of oxygen necessary to attain this end varies.

In the anæmic and in the stagnant type of oxygen lack it can be assumed that the arterial blood is carrying as much oxygen as it is capable of doing in combination with the hæmoglobin and in order to increase the amount of oxygen carried to the tissues it is necessary apart from therapeutic method directed towards improving the circulation to increase the amount of oxygen in simple solution in the blood plasma. This can only be done effectively by increasing greatly the partial pressure of oxygen in the air in the lungs. Normally the lung alveolar air contains approximately 14 per cent of oxygen, which at ordinary barometric pressures is equivalent to an oxygen pressure of approximately 100 mm of mercury. At this pressure the amount of oxygen in simple solution in the blood is 0.3 volume per cent while, assuming the percentage of hæmoglobin to be normal the amount of oxygen in combination will be 18.5 volumes per cent. If the partial pressure of oxygen be raised to 720 mm, which would occur if the subject inspired pure oxygen, the amount of oxygen in combination with hæmoglobin would remain unaltered but the amount in simple solution in the plasma would be increased to 2.2 volumes per cent. This would provide a considerable increase in oxygen available to the tissues, and would be sufficient to overcome the tissue oxygen deficiency in some cases of anæmic and stagnant oxygen lack.

As regards the anoxic type of oxygen lack, such a high alveolar oxygen pressure is seldom, if ever, necessary. The conditions met with clinically where oxygen lack of this type occurs are pneumonia, pulmonary oedema, acute bronchitis and various other acute and chronic inflammatory diseases of the lungs. In a general way it can be stated that in such conditions owing to inflammatory or oedematous thickening of the alveolar epithelium oxygen is able to pass into the blood less readily than normally. According to the severity and the extent of such abnormality a variable degree of increased partial pressure of oxygen in the alveolar air is necessary in order that normal amounts of oxygen may reach the blood. In certain clinical conditions there may be a combination of the stagnant and anoxic types of oxygen lack, such for example, occurs in conditions of congestive cardiac failure. In such circumstances owing to the cardiac lesion, the blood supply to the tissues is greatly diminished while increasing oedema of the lungs produces the anoxic type of oxygen lack, consequently the myocardium suffers more and

more from oxygen deficiency and so can less readily perform its functions, thus producing a vicious circle of the most ominous type. The relief of tissue oxygen lack of all types can be attained by increasing to a sufficient degree the pressure and, therefore, the percentage of oxygen in the alveolar air of the lungs.

Ordinary air contains approximately 21 per cent of oxygen, and in normal circumstances the alveolar air of the lungs contains some 6 per cent less. In order to raise the alveolar oxygen percentage it is necessary either (a) to increase the amounts of air breathed without increasing proportionately the metabolic demand for oxygen or (b) to increase the percentage of oxygen inspired. In order to increase the amount of air breathed some form of respiratory stimulus is necessary. The amount of increase must be large, but however large it is it is impossible to increase the alveolar oxygen percentage above approximately 18 per cent. Carbon dioxide forms the most potent respiratory stimulant and Table I shows the increase in pulmonary ventilation and in alveolar oxygen percentage which can be attained by the administration of this gas. This, however, is not a satisfactory method of dealing with the majority of clinical conditions in which there is anoxic oxygen lack. It offers, however, a valuable means of dealing with oxygen lack due to carbon monoxide poisoning.

TABLE I

Subject	Respiratory Rate	Pulmonary Rate	Respiratory Minute Volume (Litres)	Litres CO <sub>2</sub> expired per minute at 1 litre inspired air	Alveolar Air	
					CO <sub>2</sub>	O
H. W. D.	9.0	72	6.47	—	Per cent	Per cent
	10.0	72	7.35	—	5.70	14.21
	10.5	72	13.97	0.6	5.68	14.23
	10.5	70	15.5	0.7	5.53	16.62
	12.0	70	19.17	1.1	6.61	16.74
A. W. R.	11.0	70	7.1	—	5.9	14.83
	11.0	70	7.7	—	5.21	1.89
	11.0	73	13.0	0.5	6.19	16.91
	13.5	65	17.9	0.8	6.42	17.43
	15.0	70	21.2	1.4	6.87	17.65

The percentage of oxygen in the inspired air may be increased in one of two general ways. By the first the patient may be placed in a large chamber or some type of bed tent where the oxygen percentage can be raised to any required degree. In practice however it is difficult by means of the oxygen chamber to attain an oxygen percentage of more than 60, and, in any case the high initial cost, the necessity for skilled supervision, and the imperative need for elaborate precautions against fire, limit the use of oxygen chambers to comparatively few large institutions. I do not wish, however, to deprecate the use of oxygen chambers for in certain chronic respiratory diseases, where prolonged oxygen treatment is necessary, or in such severe acute conditions that the patient is unable to tolerate a mask or other ordinary means of administration, an oxygen chamber is extremely valuable.

It is possible to arrive at somewhat similar results to those attained in the chamber by "closed circuit" methods of oxygen administration. In such a method the patient inspires from a suitable apparatus (spirometer or Douglas bag) filled with the desired percentage of oxygen. By a suitable arrangement of valves the expired air passes through purifiers which remove carbon dioxide and water, and then returns to the inspired air container oxygen being added in accordance with the metabolic requirements of the patient. This amount can be gauged by the initial rate of diminution in volume of the spirometer or bag. By maintaining this volume at a constant the percentage of oxygen in the inspired air remains steady. For administering oxygen in such a manner a Benedict or Krogh metabolism apparatus is quite suitable. Such an apparatus has also been devised by Dr. Poulton. A further advantage of these two methods is that assuming the chamber or breathing circuit to be free of leaks the amount of oxygen needed to maintain a constant percentage is only that required to fulfil the metabolic requirements of the subject, an amount which would seldom exceed half a litre per minute. Although this advantage holds in practice with

\* The opening paper of a discussion on the therapeutic uses of oxygen in the Section of at the Annual Meeting of the British Association of Physicians, 1927.

"closed circuit" methods, yet in the case of the chamber the loss of oxygen due to leaks and to the necessary entry and exit of nurses and others is very considerable. In the oxygen chamber at the hospital of the Rockefeller Institute, New York, the amount of oxygen required to maintain the oxygen in the chamber at 40 per cent was approximately of the order of 5 litres a minute, and this in spite of the fact that the chamber was carefully designed and was built almost regardless of cost. Considerably larger amounts were necessary in order to maintain the oxygen percentage at approximately 60. A description of this chamber has been published by Bungei.<sup>2</sup> As regards the Guy's Hospital chamber, Campbell and Ponton<sup>3</sup> state that it was "not easy to raise the average percentage of oxygen during the twenty-four hours much above 40 per cent."

The second general method consists in the addition of oxygen to the ordinary inspired air, and, in order to know the percentage of oxygen inspired, it is necessary to have as accurate as possible an idea of the rate of oxygen flow and the total amount of air breathed. Thus, for example, oxygen administered at a rate of 2 litres a minute to a patient having a total respiratory volume of 5 litres a minute would be more effective than in a case where the total respiratory volume was 10 litres a minute. With a simple apparatus in which the oxygen flow is continuous, the oxygen flowing during the expiratory phase of respiration would be completely lost, so that the effective flow of oxygen added to the inspired air and actually entering the respiratory tract would be 1 litre a minute. In the first case the patient would be inspiring 4 litres of air containing approximately four-fifths of a litre of oxygen, and 1 litre of pure oxygen, so that the total amount of oxygen would be one and four-fifths litres in 5 litres, or 36 per cent. In the second instance the amount of air breathed would be 9 litres containing one and four-fifths litres of oxygen plus the one litre of pure oxygen in a total of 10 litres—approximately 28 per cent. The alveolar oxygen percentage would be respectively 30 and 22, very approximately. So, in order to gauge more or less approximately the effect of a given amount of oxygen, it is necessary to know the total respiratory minute volume as well as the rate of oxygen flow. If, however, the method adopted for the administration of oxygen enables the gas to be conserved during the expiratory phase of respiration, then the effect of a given rate of oxygen flow will be approximately doubled.

From these considerations it can be seen that, knowing the total respiratory minute volume and the rate of oxygen flow, it is easily possible to calculate the percentage of oxygen in the alveolar air. When this is done and compared with the actual observed alveolar oxygen percentage, a figure can be obtained which indicates quantitatively the percentage efficiency of any given method for the administration of the oxygen. Comparisons of various methods were made in this manner by Dr. Gilchrist and myself.<sup>4</sup> Table II shows figures which illustrate the results obtained. The very low figures obtained for the tube and funnel and nasal catheter methods are due mainly to the fact that only half the oxygen administered by these means enters the respiratory tract, the other half being carried away with the expired air. It is rather surprising that the nasal catheter showed figures which are only slightly better than those for the tube and funnel. It can be seen, however, that with large rates of oxygen flow a considerable increase in alveolar oxygen percentage can be obtained by both of these methods, but the low efficiency percentage indicates the very considerable wastage of oxygen necessary to attain this object.

It will be well, perhaps, to consider briefly rates of oxygen flow. Not infrequently in hospital wards, even in the wards of big teaching hospitals, oxygen is delivered from a funnel held at a varying distance from the patient's face, the gas bubbling through a wash-bottle at rates at which the bubbles can readily be counted. We have set up similar apparatus and found that the maximum rate at which the bubbles can be counted is approximately five a second. When a flow meter was placed in series with such a system and with such a rate of bubbling, it was found that the actual rate of oxygen flow was not more than a quarter of a litre a minute. Analysis of a sample

TABLE II—Showing Percentage Efficiency of Different Methods of Oxygen Administration at Various Ratios of Oxygen Flow to Respiratory Volume per Minute

Method	Rate of O <sub>2</sub> Flow L P M	Respiratory Volume L P M	Calculated Alveolar O <sub>2</sub> per cent	Observed Alveolar O <sub>2</sub> per cent	Efficiency per cent

\*The funnel was touching the nose and chin when the rate of O<sub>2</sub> flow was 2 and 8 litres a minute. It was 2 in. from the tip of the nose when the rate was 4 litres a minute.

†There was great discomfort at this rate of flow.

of alveolar air after breathing for five minutes at this rate of flow showed an oxygen percentage of only 15.2—a negligible increase above the normal. With a rate of flow of 2 litres a minute, the oxygen percentage rose to 27. At this rate the oxygen passed through the wash bottle in a continuous and vigorous stream. In general it can be said that, with the small rates of oxygen flow usually adopted, the tube and funnel and nasal catheter methods are absolutely ineffective, that the increase in alveolar oxygen percentage is so small that, apart from possible psychological effects, no benefit to the patient can possibly be attained. This probably accounts for many of the statements to the effect that oxygen administration is of little or no benefit. In the administration of other drugs, in the regulation of diet, indeed in the application of almost any therapeutic agent, quantitative methods of dosage are used. Surely with all the facilities of modern science similar quantitative methods can be used in the administration of oxygen. It is only with the certain knowledge that an effective concentration of oxygen in the inspired air or alveolar air has been obtained that it can justly be said whether or not oxygen is of benefit.

There is a further objection to the nasal catheter method. The rate of oxygen flow necessary to produce a satisfactory increase in the alveolar oxygen percentage is so large that great discomfort is caused, except in subjects where the respiratory minute volume is small and the necessary rate of oxygen flow therefore less—as, for example, in infants. For minor degrees of respiratory disturbance an alveolar oxygen concentration of somewhere between 25 and 30 per cent will be sufficient to abolish oxygen lack. This can be attained by the tube and funnel or by the nasal catheter with an oxygen flow of approximately 5 litres a minute and a respiratory minute volume of not more than 10 litres a minute.

The first widely adopted method of administering oxygen quantitatively was that of Haldane,<sup>5</sup> which was introduced during the war and used with very marked benefit for the treatment of war gas poisoning. The oxygen is delivered into a small bag attached to a mask, and remains in the bag during the expiratory phase of respiration. During inspiration oxygen is sucked from the bag, and from an additional opening in the mask sufficient amount of ordinary atmospheric air are inspired to satisfy the total respiratory requirements. During expiration the slight increase in pressure, due to the air passing out through the opening in the mask, is sufficient in ordinary circumstances to hold the oxygen back in the bag. Provided the oxygen is conserved during the expiratory phase, a saving of 50 per cent of the gas is effected. Such a rate of oxygen flow can be regulated as desired by means of a reducing valve and calibrated needle valve. It is

figures already shown in Table II it can be seen that where the rate of oxygen flow is not greater than half the respiratory minute volume this apparatus shows a very high degree of efficiency, but where the rate of oxygen flow approaches the respiratory minute volume the efficiency falls very markedly. This is due to the fact that however much oxygen is flowing a certain amount of air will be sucked through the expiratory opening of the mask. Yet in practice, on account of its simplicity the Haldane apparatus remains the most suitable for ordinary clinical use its disadvantage being merely that it is almost impossible to obtain an alveolar oxygen percentage of much more than 60 such a high concentration is however seldom necessary. A further disadvantage is that although the rate of oxygen flow can be fixed at any desired amount, yet the apparatus affords no means for determining the total respiratory minute volume. Hence, unless this is independently obtained it is impossible to calculate the alveolar oxygen percentage. In order to overcome this deficiency a modified form of apparatus was devised by Dr. Gilchrist and myself.<sup>44</sup>

The apparatus comprises a suitable cylindrical head attached with a reducing valve and a true adjustment regulating valve. From this the oxygen passes through a simple type of flow meter calibrated in litres per minute and reading up to 15 litres. From this point it passes to a bag of a capacity sufficient to hold approximately 5 litres of oxygen it then passes through a valve and thence to the mask. The valve should be of such a type as to enable the flow of gas to be observed and for this reason it seemed to us that the old fashioned type of Muller water valve would be the best. This not only acts as a valve but in addition serves to moisten the oxygen and further if it be surrounded by an outer vessel filled with hot water the stream of oxygen can also be warmed. It is not considered that warming per se is very necessary the advantage of the warming is that a larger quantity of water vapour is taken up by the gas at the higher temperature and this overcomes the tendency to uncomfortable drying of the upper respiratory passages when high percentages of dry oxygen are used. The mask has the usual pneumatic rubber pad surrounding it which enables it to be applied without any leakage. The body of the mask is fitted with three openings, through the first the oxygen passes from the Muller valve the second is an expiratory valve and the third an extra air valve which can be completely closed or opened to any desired extent. When this valve is closed and the mask is applied without leaks the flow of oxygen must be made sufficiently large to satisfy the total respiratory needs of the subject. If the rate of oxygen flow is too great the bag will become overdistended and the oxygen, instead of bubbling through the Muller valve only during the inspiratory phase will pass continuously through it the excess passing directly out through the expiratory valve on the mask.

This is what should always be done at the commencement of administration. Before applying the mask to the patient the oxygen should be turned on at a rate slightly greater than what is considered a probable respiratory minute volume and the bag allowed to become well filled. If the mask before the oxygen is turned on be applied to a patient suffering from oxygen lack the discomfort of the patient will be greatly increased and he will not infrequently adopt a psychological attitude which will render the further use of the mask very difficult. Normally when a mask is applied the subject immediately consciously or unconsciously experiences the feeling that his air supply is going to be restricted and he instinctively takes a big breath. Unless there is air or oxygen passing through the inlet tube in sufficient quantity to satisfy his demand the state of mind mentioned above will be established hence the necessity for a very liberal supply of oxygen during the first minute or so. If the rate of oxygen flow be less than the respiratory minute volume, the extra air valve mentioned above being closed then the bag will become more and more empty until a point is reached where before completion of an inspiration, the bag will be completely empty. By watching the bag and adjusting the rate of oxygen flow so as to avoid the two alternatives—namely, (1) wastage of oxygen through over-

filling the bag and (2) failure to satisfy the respiratory needs due to emptying the bag—a rate of oxygen flow can easily be attained which is just sufficient to satisfy the respiratory requirements of the patient. A reading of the flow meter at this point indicates very approximately the patient's respiratory minute volume. In the circumstances the patient will be breathing pure oxygen, which for therapeutic purposes is not usually necessary, this being merely a preliminary proceeding to estimate approximately the patient's respiratory minute volume and so determine the rate of oxygen flow necessary to produce any desired alveolar oxygen concentration.

TABLE III—Showing maximum percentage of oxygen of final air in the alveolar air at various minute volumes of respiration when oxygen at different rates of flow is added to the inspired air—for example a subject breathing at 6 litres per minute and with 3 litres of oxygen per minute added to the inspired air should have an alveolar oxygen percentage of 51

Table III taken from the paper by Gilchrist and myself shows the alveolar oxygen percentages produced by a combination of respiratory minute volume and rate of oxygen flow within normal limits but in general it can be said that with an apparatus such as this or that of Haldane, which conserves oxygen during the expiratory phase, a rate of oxygen flow equal to one-fifth of the respiratory minute volume will raise the alveolar oxygen percentage to 30. Where it is one-fourth the percentage will be 34 one-third 41, one-half 67 and where the rate of oxygen flow equals the respiratory minute volume the alveolar oxygen percentage rises to its maximum of slightly more than 94 per cent the remaining gas being the normal 5 to 6 per cent of carbon dioxide. The preliminary administration of pure oxygen at a rate equal to the respiratory minute volume should immediately abolish the urgent symptoms of oxygen lack unless the latter be of the anemic or stagnant type of a very severe degree. Much lower concentrations are usually sufficient. Therefore the rate of oxygen flow is then reduced to such a proportion of the respiratory minute volume as is required to produce whatever alveolar oxygen percentage may be considered necessary. The extra air valve is then opened to the required extent. If too much extra air is given, the normal amount of oxygen will not be sucked through the Muller valve with each inspiration, and the bag will tend to become overfull. If too little extra air be given the reverse will be the case, and the bag will be sucked empty. So that the same observation of the bag and the flow of oxygen through the Muller valve is necessary in adjusting the extra air orifice as in the initial determination of respiratory minute volume.

The description suggests that the method may be unnecessarily complicated but it works well in practice. Precise knowledge of the alveolar oxygen percentage is much more than a mere academic nicety not only is there the satisfaction of producing a definite effect but also the percentage of alveolar oxygen necessary to abolish the symptoms of oxygen lack affords a quantitative indication of the severity and extent of the pulmonary damage. Where not more than 40 per cent of alveolar oxygen is necessary—that is to say, where the rate of oxygen flow is not more than one-tenth of the respiratory minute volume—the mask can be dispensed with, for it has been found that the forked nasal tube, described by Gilchrist and myself,<sup>44</sup> is perfectly efficient for such rates of oxygen flow. We have found this to be the case even where the patient has fallen asleep and

breathed partly or mainly through his mouth. The forked nasal tube can, of course, be used only in cases where there is no nasal obstruction.

Full descriptions of the symptoms of oxygen lack will be found in the published works of Haldane,<sup>7</sup> the monographs of Lundsgaard and Van Slyke,<sup>8</sup> Means,<sup>9</sup> and Meakins and myself.<sup>10</sup> Oxygen administration is necessary mainly in the treatment of anoxic oxygen lack, and here the ideal is to administer just sufficient oxygen to restore the oxygen saturation of the arterial blood to its normal level. This requires facilities for blood-gas estimations which are not generally available. There are, however, other and simpler criteria of adequate oxygen administration.

The first criterion is the abolition of cyanosis. It is possible, however, that this may occur before the oxygen lack has been completely abolished. Moreover, a significant degree of oxygen lack may exist without any appreciable amount of cyanosis, for, as has been shown by Lundsgaard and Van Slyke,<sup>8</sup> cyanosis, apart from that of the stagnant type, does not occur with an arterial oxygen saturation of more than 80 to 85 per cent, a moderately severe degree of oxygen lack, the normal arterial oxygen saturation being approximately 96 per cent. Hence it can be seen that rather more oxygen should be given than is just sufficient to abolish cyanosis completely. Moreover, as Meakins<sup>11</sup> has indicated, the aim in the treatment of acute respiratory conditions is to prevent rather than to treat cyanosis and oxygen lack.

The second criterion is the relief of dyspnoea. This cannot always be brought about. In many respiratory diseases the respiratory embarrassment is due to causes which continue to operate after the oxygen lack has been abolished by effective oxygen administration—for example, pleural friction. It can, however, be dogmatically asserted that the respiratory embarrassment is always aggravated by oxygen lack. Hence the effect of oxygen administration will always be to produce a certain amount of relief to dyspnoea, although in certain cases the subjective relief may not be very great, especially in those cases where the oxygen lack is accompanied by carbon dioxide retention. A very good example of different types of oxygen lack is given in the experiments on rapid breathing by Binger, Brown, and Burch.<sup>12</sup> These observers produced pulmonary embolism in two different ways. In the first case they produced embolism of the pulmonary capillaries by the intravenous injection of a suspension of starch granules. After a certain point a marked increase in respiratory rate occurred, frequently associated with arterial oxygen deficiency. When this oxygen lack was abolished by oxygen administration there was a certain amount of reduction in the respiratory rate, but to nothing like the normal level. Apparently some reflex, probably due to irritation of the branches of the afferent vagi in the lungs, was concerned in the maintenance of this abnormally rapid rate. In the other series of experiments embolism of the larger branches of the pulmonary arteries was produced by the introduction of seeds of various sizes. In this case increase in the respiratory rate also occurred, associated with anoxaemia, but on abolition of the anoxaemia by oxygen administration the respiratory rate returned to its normal level. In certain conditions, therefore, oxygen administration may produce a fall in respiratory rate associated with relief of dyspnoea. Such, however, is not necessarily the case, and the continuance of respiratory embarrassment is not always an indication that the oxygen lack has not been effectively abolished and that oxygen therapy has been ineffective.

A third, and probably the most reliable, criterion of successful oxygen administration is a fall in pulse rate. This occurs even in normal individuals when increased percentages of oxygen are breathed, while in conditions of oxygen lack, of both the anoxic and stagnant types in congestive cardiac failure, effective oxygen administration produces quite considerable and significant diminutions in pulse rate, the only exception, so far as I am aware, being in a case of circulatory failure with heart-block, described by Meakins and myself,<sup>10</sup> where administration of oxygen appeared to restore the conduction of the cardiac impulse and the pulse rate was approximately doubled.

Barach,<sup>13</sup> in assessing the value of oxygen therapy in the treatment of pneumonia, notes the diminution of restlessness, promotion of sleep, and the tendency to a delirium. It cannot, however, be too strongly emphasized that the changes in the central nervous system of a delirium is a manifestation of the result of oxygen lack and that they should be prevented by the early administration of oxygen. Once these changes have occurred, relief of oxygen lack may prevent their further development, but does not always abolish them. As a physician, I may I appeal for caution in the use of stimulant drugs in the treatment of pneumonia. These can only increase the excitability of the central nervous system and intensify the demand of the tissues for oxygen. Sedatives may, however, be safely employed, provided that oxygen lack is prevented by effective oxygen administration.

In the treatment of acute respiratory diseases the value of oxygen administration is to tide the patient over the period of functional deficiency and so prevent damage to the central nervous system, myocardium, and other tissues. In this way it may be compared with the restriction of carbohydrate intake in diabetes and of nitrogenous intake in certain types of acute nephritis. Barach,<sup>13</sup> writing of the effect of oxygen administration in lobar pneumonia, states that "the value of oxygen treatment is felt to be supportive and not curative. In severe dyspnoea with cyanosis oxygen treatment has appeared to prolong life until such a time as the immunity mechanism was able to accomplish recovery."

Similarly, in the treatment of the respiratory embarrassment of congestive cardiac failure, the prevention or relief of anoxic anoxaemia will prevent further myocardial damage, and tide the patient over the critical period until the measures directed towards circulatory improvement have their effect.

Lastly, the value of oxygen administration in the treatment of chronic respiratory diseases may be briefly mentioned. Brieff and his co-workers<sup>14</sup> have found that many patients suffering from chronic disability resulting from air gas poisoning were permanently relieved by temporary residence in the oxygen chamber. Similar encouraging results have recently been reported by Campbell and Ponton<sup>15</sup> in cases of chronic bronchitis and emphysema. Dauterband<sup>16</sup> has shown the value of oxygen in relieving dyspnoea and diminishing the amount of cough and expectoration in cases of pulmonary tuberculosis.

Knowledge of the functional changes in chronic respiratory diseases is all too scanty, and the means at present adopted for their relief all too few. Investigation of the blood gases and of the respiratory exchange affords quantitative evidence of the functional deficiency, while estimations of the vital capacity and lung volume, combined with other simple physical measurements, indicate the extent and severity of the structural changes. All these investigations are necessary for an exact estimate of the value of any particular method of treatment. The relief of functional deficiency, even when only temporary, allows various healing and restorative processes to come into play and breaks what is frequently a vicious circle. In view of the very great importance of chronic respiratory diseases as causes of ill health and of economic loss, it is not possible to appeal too earnestly for more extensive investigation, which would involve active co-operation between physiologists, immunologists, and clinicians. The first is a fruitful one, and the workers would have before them the certainty that their labours would result in the relief of much suffering.

## II—INDICATIONS FOR OXYGEN THERAPY

BY

W. T. RITCHIE, M.D., F.R.C.P. Ed.,  
Physician to the Royal Infirmary, Edinburgh

ALTHOUGH the symptoms and signs of anoxæmia are protean, it is recognized that the two chief clinical manifestations of general anoxæmia are dyspnoea and cyanosis, that the onset of the former usually precedes that of the latter and that dyspnoea is often so urgent as to call for speedy, or even immediate relief. Chronic anoxæmia of lesser degree may interfere gravely with the functional efficiency of various organs and tissues, and ultimately lead to structural changes in them.

It is mainly in the hope of relieving severe dyspnoea that oxygen is administered. If dyspnoea and cyanosis were due solely to deficient oxygenation of the blood in the lungs it might be thought that the deficiency would be met by adding oxygen to the inspired air, and thus restoring to a normal level the oxygen tension of the alveolar air and the oxygen saturation of the arterial blood. Unfortunately the problem is not so simple, nevertheless this is the essential basis of oxygen therapy.

The methods of administering oxygen are far from satisfactory. The volume of oxygen that is delivered from the cylinder is only approximately known, no knowledge regarding the amount inspired by the patient while that which diffuses into his pulmonary capillaries is largely a matter of conjecture. In the administration of oxygen a common fault is to give too little. If oxygen is required we must give ample—not less than 2 litres a minute. This corresponds approximately to a free, rapid bubbling of the gas through water in a wash bottle. Oxygen is rapidly absorbed and rapidly consumed; there is no mechanism for the storage of oxygen in the fluids or tissues of the body. Any good effect derived from oxygen therapy is extremely evanescent, often lasting for not more than a few minutes. If oxygen is required it ought to be administered as continuously as is possible, to administer it for a few minutes every few hours or even several times an hour is of very little if any value. I never use a glass funnel held some inches from the face; a moulded glass face mask is more efficient and it is less irksome to the patient than either an oral or nasal tube. Haldane's apparatus is the most economical and reliable, I use it regularly in hospital practice.

Clinical observation indicates that oxygen therapy relieves dyspnoea and cyanosis in some patients; in them the fault must have been deficient oxygenation of the blood in the pulmonary capillaries. In other cases in which oxygen therapy is of no value the free entrance of oxygen into the alveoli may be prevented owing to various causes—such as tracheal compression, laryngeal or bronchial spasm, pulmonary emphysema, accumulation of secretion in the air passages or the presence within the alveoli of dropsical fluid or inflammatory exudate.

Again, oxygen therapy may fail because the dyspnoea is due to causes other than faulty oxygenation or the blood in the lungs; it may be the result of a pathological increase of metabolism as in hyperthyroidism. Here the abnormality in respect of oxygen is not a lack in the supply of oxygen to the tissues but their excessive consumption of oxygen. Moreover, the exophthalmic patient whose heart is sound is not dyspnoeic when at rest. Oxygen is likewise of no service in the dyspnoea of uræmia, in which the tissues receive too little oxygen because the lack of bromoglobin involves an inadequate transport of oxygen to them. Even though the uræmia be profound and causing those structural changes with which the physician and pathologist are familiar the patient is seldom breathless while he is at rest. Diabetic dyspnoea, the air hunger of Kussmaul, has certain distinctive features: the depth of the breathing is greatly increased, the rate is seldom raised. The dyspnoea resembles that following the breathing of air containing an increased content of carbon dioxide and is therefore presumably not due to want of oxygen. Dyspnoea in diabetes is a sign of grave acidosis; it is not due to anoxæmia but to increased hydrogen ion concentration of the blood with consequent disturbance of the acid base

balance, and the administration of oxygen affords no relief. The dyspnoea of the terminal phases of renal disease has other characteristics, one of which is that the respirations tend to become periodic. Periodic, or Cheyne-Stokes breathing is seen also in other states notably in those which cause great increase of intracranial pressure. Oxygen is not a satisfactory remedy for the dyspnoea of renal disease; the primary cause of which is probably a retention acidosis not an anoxæmia. In hydropic cases pulmonary oedema must gravely interfere with the diffusion of oxygen from the alveolar air into the pulmonary capillaries and in my experience the addition of oxygen to the inspired air does not lessen the dyspnoea. Cheyne-Stokes breathing when artificially induced, is one of the late manifestations of oxygen want, and can be relieved by the inhalation of carbon dioxide or oxygen, when it is primarily of cerebral origin it may be abolished while the patient is breathing air to which a little carbon dioxide is being added but the breathing quickly becomes periodic again after the additional carbon dioxide has been discontinued. In the same case oxygen, too will render the breathing regular, but the benefit, though more lasting than that of carbon dioxide is again of short duration. Thus, to be of benefit, the administration of oxygen must be practically continuous.

Oxygen therapy is not indicated in very rapid breathing (tachypnoea) without dyspnoea, such as was not infrequently observed during the war in cases of "shell shock" and disorderly action of the heart, and oxygen is neither needed nor beneficial in the condition usually termed "hysterical dyspnoea," of which the following is an illustrative case.

A young woman of nervous temperament collapsed soon after a sudden fright. The face was ashen grey with a slightly cyanotic tint in the lips and ears the pulse rapid and feeble, the blood pressure low and the breathing so shallow and rapid as to recall that of a pupa panting in the sun. She looked as if she might die at any moment yet there was no organic disease. Oxygen was administered by Haldane's apparatus without any benefit. The addition of a little carbon dioxide to the inspired air at once lowered her respiratory rate to 24 a minute, the breathing became deeper and all the urgent signs vanished. Some weeks later she was readmitted in a similar urgent state. While breathing air enriched with oxygen the rate of breathing rose from 45 to 59, but the addition of carbon dioxide lowered it from 43 to 33 a minute.

I conclude that the initial fright had caused deep breathing, an excess of carbon dioxide had been eliminated, and the ratio between the carbonic acid in the blood and the plasma bicarbonate had been disturbed, the blood reaction being shifted towards the alkaline side. The disturbance was therefore an alkalosis from loss of carbon dioxide; it is sometimes termed "respirin" but is more aptly designated "hypocapnia." In such a condition oxygen is of no avail.

In the treatment of circulatory failure oxygen plays but a minor part. The myocardium is enfeebled and the circulation is retarded. The blood passing slowly through the capillaries becomes unduly desaturated in respect of oxygen, and has added to it an excess of carbon dioxide. Thus the anoxæmia of circulatory failure is primarily a stagnant anoxæmia. So long as the pulmonary circulation remains efficient the blood passing through the lungs becomes again fully oxygenated, enrichment of the inspired air with oxygen does not increase the oxygen saturation of the arterial blood. In the later stages of circulatory failure with persistent dyspnoea even at rest, orthopnoea, cyanosis, and dropsy the lungs are the seat of venous congestion and oedema. The patient's breathing has become more rapid and less deep, the vital capacity is lowered, and the oxygen content of the alveolar air has fallen. The anoxæmia which now ensues is in itself harmful and may cause the breathing to become more shallow and rapid. Thus a vicious circle may be established. It is in this later stage of circulatory failure, with urgent dyspnoea, that I always administer oxygen, though realizing that neither on the circulatory failure nor its cause has it any direct influence. Oxygen therapy is more likely to be beneficial, lessening both cyanosis and dyspnoea when intense dyspnoea has begun suddenly and recently, as in the early phases of auricular flutter, paroxysmal auricular fibrillation, and paroxysmal tachycardia, than when it has

developed gradually and lasted for a considerable time. In the former group of cases oxygen may afford some relief until the paroxysmal disorder of the heart terminates spontaneously or until by appropriate means we have controlled the ventricular tachycardia or restored the normal cardiac rhythm. Even in the group of chronic cases there are some, notably the chronic fibrillators with a very rapid ventricular rate, in whom oxygen lessens the cyanosis and dyspnoea, and, I believe, helps to tide the patient over the phase of grave cardiac failure. In chronic myocardial failure associated with a normal cardiac rhythm there is seldom any benefit to be derived from oxygen therapy.

It is evident that the administration of oxygen can have no influence on the cyanosis due to a congenital septal defect of the heart so large as to permit of much venous blood (at least 38 per cent according to Lundsgaard and Van Slyke) being shunted from the right to the left side of the heart. We are therefore safe in concluding that if the cyanosis of congenital heart disease disappears while oxygen is being administered there is certainly no large septal defect. The cyanosis of congenital pulmonary stenosis may vanish during the time of oxygen administration, but the effect is so transient that it cannot be regarded as of any therapeutic value.

It is in disease of the respiratory system that imperfect oxygenation of blood in the lungs, with resultant dyspnoea of severe degree and the need for oxygen therapy, is most frequent. The anoxaemia may be due to two factors: (1) lessening of the volume of air which enters the bronchioles, as in tracheal compression and bronchial asthma, and (2) interference with the diffusion of oxygen through the alveolar walls into the pulmonary capillaries, as in acute pneumonia and pulmonary emphysema. Both factors doubtless operate in causing the anoxaemia of pulmonary emphysema and acute pneumonia. In emphysema marked dyspnoea and deep purple cyanosis may persist even while the patient is kept at rest in the semi-recumbent posture, and the frequent administration of oxygen then affords more relief, even though temporary, than is obtainable by any other means.

It is in acute pneumonia that oxygen is most often administered. More than thirty years ago I learned from that wise physician of great clinical experience Sir James Affleck that oxygen therapy may be of great value in acute lobar pneumonia. To-day that opinion is still true. All recent research on the oxygen saturation of the arterial blood in pneumonia, with a demonstrable rise of the percentage oxygen saturation from an unduly low level to one approximately normal during the administration of oxygen, is in harmony with the observations made long since at the bedside that oxygen may be helpful in acute pneumonia.

Every pneumonic patient is dyspnoeic, but it does not follow that he needs oxygen. In the treatment of acute pneumonia oxygen is not my first line of defence—my sure shield is good nursing—not is it my second or even my third line. Nevertheless just as the special constable had his part to play during the war, so, too, my oxygen therapy help to some extent in the fight against pneumonia. Many patients make an uninterrupted recovery, having never needed oxygen, digitalis, stimulants, or hypnotics. There is one indication for the administration of oxygen in pneumonia—an indication which should never be neglected—and that is cyanosis. There may be differences of opinion regarding the relative parts played by cardiac, vascular, and pulmonary factors in the development of the cyanosis, but there can be no question that the administration of oxygen may relieve both the dyspnoea and cyanosis, and therefore by combating anoxaemia tend to obviate cardio-vascular failure. The faintest trace of cyanosis in the lips, ears, or nose is a call for oxygen. The call becomes urgent if the cyanosis is pronounced, when that ominous combination of pallor and cyanosis develops it is usually too late to hope for much benefit from oxygen therapy. If oxygen is indicated in pneumonia it should be given freely and as continuously as possible. It is undoubtedly more valuable in acute lobar pneumonia than in acute broncho-pneumonia.

While I am an advocate of oxygen therapy in pneumonia, it has never been my good fortune to observe any of the magical effects described by some writers. Acute pneumonia is always a serious disease. During a period of four years ending October, 1926, 895 cases of acute pneumonia (including acute broncho-pneumonia) were treated in the Edinburgh Royal Infirmary. Of patients who were in the first three decades, 92 per cent recovered, of those in or after the seventh decade only 35 per cent recovered. Anoxaemia is only one of many factors with which we have to reckon in pneumonia. At the extremes of life, in the destitute, the intemperate and the obese, and especially in profoundly toxic cases such as those during the epidemic of 1918-19, oxygen therapy is usually powerless to avert a fatal issue.

### DISCUSSION

Dr. R. HARRIS (London) said that he had examined the oxygen content of blood obtained by arterial puncture in various conditions, including pneumonia. It was remarkable that there was no drop in the oxygen saturation of arterial blood in this condition. This implied that the circulation through collapsed portions of lung must be extremely small, otherwise the arterial stream must inevitably be polluted with venous blood. He showed lantern slides illustrating experiments in which he had administered oxygen by various methods, and determined the oxygen content both of alveolar air and of arterial blood. He agreed that the funnel method was useless. He had obtained good results by the nasal catheter method though he found that if the gas were given at too great a rate much discomfort was produced. He showed that a small but not a negligible rise in arterial oxygen tension could be produced by such small amounts of the gas as 0.75 to 1 litre a minute when given by nasal catheter. He added that eating, coughing, and expectoration were not interfered with by the presence of the catheter. He discussed some satisfactory results which he had obtained with a mask he had devised, and which was demonstrated.

Professor C. W. GREENE (Missouri, U.S.A.) emphasized the necessity of continuous oxygen therapy from its commencement until the crisis which it was intended to combat had passed. The physiological reactions to an increased supply of oxygen were remarkably prompt. In processes of anoxaemia induced on normal men or animals, if, when the limit of endurance was approaching, a momentary flood of oxygen was supplied, then the heart slowed, the blood pressure decreased, and the respirations became almost normal in rate and depth—all in a few seconds; the skeletal motor reactions, the alimentary motor innervation, and other less easily followed asphyxial nerve reactions quieted down. When the anoxaemic condition was re-established these reactions were promptly returned. In disease—during anoxaemic crisis in lobar pneumonia, for example—the same conditions operated, modified by the toxæmia and the particular pathological condition of the patient. The danger of interruption of the extra oxygen supply is that the patient might not stand the shock of the sudden recurrence of the anoxaemic nervous reactions.

Dr. CARL H. CRITCHE (Mayo Clinic) stated that the oxygen treatment of pneumonia had been instituted during the last few years by Drs. Baerthly and Weber at the Mayo Clinic. They had used both the oxygen tent and the oxygen tent with success, though the latter was less complicated and was more suitable for ordinary hospital practice. By such means the cyanosis in pneumonia could usually be completely controlled. If treatment was continued for a sufficient period it might improve the patient's life. Most striking features were the reduction in temperature and the decrease in the fever. The reduction in the pulse rate and the decrease in the respiratory rate, however, emphasized the fact that anoxaemia was not the only factor in the mortality from pneumonia, and that by estimating also the relative importance of the other factors that the final value of oxygen therapy could be determined.

# THE RELATION OF THE SEX OF OFFSPRING TO THE TIME OF COITUS DURING THE OESTROUS CYCLE

BY

F A E CREW, M.D. D.Sc. PH.D., FR.S.E.,  
Animal Breeding Research Department University of Edinburgh

THREE are many who hold the opinion that in the case of the human as well as in other animals the length of time which elapses between the extrusion of the ovum from the ovary and its fertilization by the sperm is a decisive factor in determining the sex of the resulting individual. This hypothesis was elaborated at length by Thury (1863-1864), who maintained that an ovum when first extruded was female in respect of its potentialities, but that at some point during its passage along the genital tract it became male. Fertilization immediately after ovulation yielded a female, fertilization some time later yielded a male, and fertilization at points between these times resulted in the production of intersexual forms. Thury, applying this hypothesis to the problems of practical animal breeding, was able to claim that, in the case of cattle, service during the earlier phases of oestrus yielded a preponderance of heifer calves, whereas service towards the end of oestrus resulted in the production of an excess of males. Thury's hypothesis was accepted and endorsed by Braus (1871), Guirard (1903), and Bell (1914). But it is reasonable to question the validity of these observations, since it is now known that it is a matter of considerable difficulty to recognize the exact stage of oestrus exhibited by an animal such as the cow. Moreover, the exact relationship of oestrus and ovulation in these forms is not clear even yet.

It is the case, however, that recent work has revealed considerable evidence which seems to show that sex reversal of the egg before fertilization does occur in certain forms. The experiments of Hertwig (1906-1912), of Kishakovitch (1910), and of Witschi (1914) have shown, for example, that delayed fertilization and also the exposure of the ovum of the frog to high temperature before fertilization lead to a profound disturbance of the sex ratio among the resulting generation. If the male frog was permitted to fertilize half of the eggs of the female and was then removed, to be replaced after an interval to fertilize the remaining eggs, after the lapse of eighty-nine hours none but male offspring were obtained from the second half. It was established that this result was not due to a selective fertilization, to a sexually selective mortality among the embryos, or to the abnormal extrusion of the X-chromosome from the ovum during its maturation. The correct interpretation of the results would seem to be that some 50 per cent of the eggs were fertilized by X-chromosome-bearing spermatozoa to become genetic females (XX in chromosomal constitution) but that the conditions of the experimentation were such as to transform them into individuals with the characteristics of the male, the sex-chromosome constitution of the zygote being overridden by the effects of delayed fertilization upon the metabolism of the egg before fertilization. King (1912) has shown that desiccation of the toad's egg yields exactly opposite results. She obtained 87 per cent of females in an experiment in which the mortality among individuals of unknown sex was insignificant. The interpretation of her results would appear to be similar.

It has been found by Whitman (1919) and Riddle (1912, 1916) that the mating of pigeons and ringdoves belonging to two widely different zoological families results in the production of male offspring only, and that female offspring alone were obtained from the eggs of doves which had been forced to lay excessively and at an abnormally rapid rate. In birds the female is the digametic sex. Riddle was able to show that eggs which yield males can be distinguished from those which yield females, that males are associated with eggs of smaller size, higher water content, and less stored energy, and that the production of more but males or of none but females is associated with the antecedent production of eggs of one or of the other kind. He submits

that delayed fertilization leads to an increased metabolic rate in the egg and that a high metabolic rate leads directly to the development of a male type physiological state and characterization. Wide crossings involve the pooling of hereditary factors which in their action lead to the establishment of one or other kind of metabolic level, male or female, in the zygote. Extending his conclusions to the case of cattle, Riddle suggests that the greater production of males from eggs which have remained unfertilized for a period of hours is almost certainly correlated with an increased water content which the eggs obtain before fertilization. He grants that it is not established that the mammalian ovum does indeed take up water from the fluid it encounters in the reproductive passages, but points out that this is so in the case of every amphibian, reptile and bird so far examined. However, it still remains to be shown that what applies to the amphibian applies also to the case of the mammal.

Russell (1891) had collected data relating to the sex ratio of calves according to the time of service during the oestrous period, and this investigation was continued and extended by Pearl and Parsley (1913), who published the following data:

TABLE I

Time of Coitus	Total Offspring	Males	Females	Sex Ratio
Early in oestrus	243	123	125	53.4
Middle of oestrus	125	67	58	115.5
Late in oestrus	107	65	42	154.8
	475	255	225	113.3

From these figures the authors concluded that the time of service had an appreciable influence upon the sex ratio. In a later paper by Pearl (1917), however, additional data were considered, and the conclusion reached that there was no definite or permanent relation between the time in the heat period at which the cow was served and the sex of the offspring. The commonly held opinion of the breeder and the suggestiveness of the earlier data of Pearl and Parsley were to be regarded as unsoundly based on insufficient statistics, and the relation of time of service and sex as purely accidental and not significant. It is impracticable for private breeders accurately to record the beginning of oestrus, the onset of activity of the cow towards the bull cannot be regarded as a trustworthy criterion of the onset of oestrus.

In the case of the rat, if the methods of Long and Evans (1922) and of Slonaker (1924) are employed to detect the onset and progress of the oestrous cycle, it is eminently possible to ensure that coitus shall occur at any particular point during this cycle. In the rat the vagina is moist and of a pinkish colour during the di-oestrous phase of the oestrous cycle. During the phase of pro-oestrus, oestrus, and met-oestrus on the other hand the vagina is dry and whitish, and the vaginal lips are more or less swollen. Long and Evans have shown that through the systematic examination of vaginal smears it is possible to follow exactly the course of the oestrous cycle. For purposes of description it was found to be convenient to divide the cycle into stages. In stage 1 the vaginal smear consists solely of medium uniform sized epithelial cells, whilst the lips of the vagina are somewhat swollen. This stage lasts for ten to fourteen hours. In stage 2 relatively few cornified cells are present in the smear. The vagina is patent and its lips are swollen and of a characteristic purple colour. The onset of this stage is sudden, the change from stage 1 being complete in two to three hours. This stage lasts twelve to thirteen hours and it, together with the next stage, corresponds to true oestrus. In stage 3 the smear consists of large numbers of cornified cells, many of them cohering to form large clumps. The swelling of the vaginal lips is receding. This stage lasts twelve hours. True oestrus, therefore, occupies some twenty-four to thirty-six hours. In stage 4 leucocytes make their appearance in the smear which now consists of cornified cells and leucocytes. The lips of the vagina are no

\*A paper read in the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association in Edinburgh 1927.

longer swollen. This stage lasts four to eight hours. In di-oestrus, lasting fifty to sixty hours, the smear consists of epithelial cells and leucocytes.

Sloniker, using the revolving cage, was able to show that the peak of physical activity of the rat coincided with the cornified cell stage of Long and Evans, and Cooley and Sloniker, employing these methods of estimating the exact stages of the oestrous cycle in the albino rat at which coitus was noted, carried out experiments designed to examine the relation of the time of service during the oestrous cycle and the sex ratio. They found that their results showed no appreciable difference in the sex ratio among offspring of matings during early and late oestrus. A ratio of 114.6 males per 100 females resulted from matings during early oestrus, one of 110.5 100 from those during late oestrus. The difference, though suggestive, is not significant, when the numbers of litters considered are taken into account.

In the human it is now generally accepted that ovulation occurs fourteen to eighteen days after the first appearance of the menses. At the time when most of the data concerning the relation between the time of coitus during the intermenstrual period and the sex of the child were secured, little or nothing was known concerning the correlation of menstruation and ovulation, and so many of them are not really useful.

The observation that the Jews exhibit a high secondary sex ratio has been explained on the ground that coitus is forbidden during the first week after menstruation, and that the ovum, therefore, overripe and potentially male when fertilized. But Pearl and Sulman (1913) failed to find any evidence that in the human the time of fertilization of the egg relative to the menstrual period had any influence upon the sex ratio among the offspring. There are data, however, which seem to suggest that such a correlation does exist. Both Siegel (1916) and Fuist (1886), for example, found that impregnations during the earlier days of the intermenstrual period yielded an excess of males, whereas later impregnation gave a preponderance of females, though Pivl (1916), on the other hand, did not observe this difference. Their data are tabulated below. Freeborn's (1916) figures show an excess of females in the case of impregnation during the first half of the intermenstrual period, an excess of males from those during the second half. Bolaffio (1922), on the other hand, noted exactly opposite results.

TABLE II

No of Cases	1-9 Days after Beginning of Menses			10-14 Days after Beginning of Menses			15-22 Days after Beginning of Menses			Authority
	♂♂	♀♀	Sex Ratio	♂♂	♀♀	Sex Ratio	♂♂	♀♀	Sex Ratio	
80	37	7	528 100	4	9	44 100	3	20	15 100	Siegel
193	40	18	222 100	23	28	82 100	27	33	82 100	Fuist
581	136	111	122 100	69	62	111 100	71	67	106 100	Pivl

The evidence is distinctly conflicting. Ewart (1922) has pointed out that one source of error common to all the above observations is their neglect of the fact that male fetuses at birth are some five to six days older than female foetuses. Siegel (1921) acknowledges the validity of this criticism, and an examination of his records showed that the average length of gestation of males was 272.6 days, whereas that of females was 267.5 days.

The subject is of such interest that it was thought to be desirable to undertake further experimentation. The albino rat was chosen as experimental material, six males from one and the same litter were used. They belonged to a strain which habitually had given an unexceptional average sex ratio (105.4 100 for a four-year period). One hundred females were used; they all belonged to the same strain as the males, being all related and line bred. The experiment was carried out during the period May to September. The experimental animals were maintained under uniform conditions in the colony house and the diet was the standard diet given to all the general stock.

The progress of the oestrous cycle was recorded by the method of Long and Evans. A drop of saline was placed on a microscopic slide, a metal spatula moistened with saline, was inserted 1.5 cm. into the vagina, and the vaginal wall gently scraped. The spatula was then stirred in the drop of saline on the slide and thus examined under a low-power microscope.

There are certain matters which have to be borne in mind in experimentation such as this. The older the animal the longer is the oestrous cycle, but oestrus proper is of longer duration in younger females. This usually begins in the late afternoon and continues throughout the night and the earlier part of the following morning. Service near the end of oestrus proper is effected only with difficulty in many instances, the female being at that time unreceptive. Further, the female will on occasion accept the male three to five hours before the oestrous cycle begins, so that it is very necessary to recognize the particular phase of the cycle by means of vaginal smears before coitus is allowed. By service early in oestrus is meant coitus during the first three hours of true oestrus, by later service, coitus during the last three hours of true oestrus, when cornified cells fill the microscopic field.

Fruitful coitus can be recognized by the presence of sperm in the post-coital vaginal smear, by the presence of the bouillon vaginalis and by the increase in weight of the female. She gradually becomes heavier and heavier up to the fiftieth day, and thereafter the further increase in weight is rapid in time pregnancy. Pseudo-pregnancy is not uncommon, however, more particularly in the case of coitus during late oestrus, and is to be recognized by the reappearance of oestrus fifteen days after service.

Allowances have to be made for a possible swing of the sex ratio with the chronological order of the pregnancy. In the case of the human there is clearly a relation between the age of the mother and the number of the pregnancy. Primiparae are usually 20 to 30 years old, second third and subsequent pregnancies occur in women over 30. Parkes (1924), for example, has shown that two thirds of primiparous pregnancies occur in women under 28 years of age, second and third pregnancies occur mainly between the ages 23 and 32, and fourth pregnancies occur between 28 and 37. It is recognized that the sex ratio swings with the chronological order of the pregnancy. It is higher in earlier pregnancies (Newcomb, 1904; Alford, 1872; Winckel, 1903; Hecker, 1874; Jattle, 1919). This swing may be related to the number of the pregnancy, to the increased age of the mother, or to both of the factors. Cooley and Sloniker (1925) and King (1915) have shown that this rule of a decreasing sex ratio with increase in the mother's age applies also to the rat, and Copeman and Parsons (1904) have shown that it holds also in the case of the mouse. In the present experiments it was decided, therefore, to consider only the third litter of each of the females. There is a progressive lengthening of the gestation period with succeeding pregnancies in the case of the rat. The second is some eight hours longer than the first, the third some six to twenty-four hours longer than the second. Coitus early in oestrus is associated with a somewhat longer gestation period than coitus late in oestrus, as would be expected, since it involves a longer interval between coitus and fertilization. The results of the experimentation may be tabulated as follows.

TABLE III

No of ♀♀	Time of Coitus	Total Litters	Female Litters	Total Offspring	Average Litter	♂♂	♀♀	Sex Ratio
59	First three hours of oestrus proper	35	15	189	5.4 ± 0.13	68	51	134 100
50	Last three hours of oestrus proper	23	22	159	5.7 ± 0.12	77	82	93 100
		63	37	348	5.53	145	133	109 100

The conclusions which emerge from this study are that it is true, with numbers that are much too small to be of any real significance—are entirely negative. It is

remembered that it is wellnigh impossible for any one investigator to conduct experimentation on a sufficiently large scale and that it is therefore desirable that experiments of this kind should be multiplied so that out of a considerable series adequate data may be secured. So far as they go the present figures tend to support the contention that the time of service in relation to the oestrous cycle is a factor of no importance in the matter of the determination of sex in the mammal.

#### Summary

In an experiment designed to examine the sex ratio among individuals resulting from coitus during the first three hours and during the last three hours of oestrus respectively in the rat no difference was noted between these two groups.

#### Discussion

Dr JAMES YOUNG (Edinburgh) thought that it was impossible to discuss Dr Crew's paper until he had had time to read it and digest it. He looked forward to a further series of investigations by Dr Crew of an even more complete nature.

The PIR IDEY (Dr Haig Ferguson) complimented Dr Crew on his most interesting paper but was sorry that it should be thought that the mark was the product of still eggs.

Dr CREW, in reply, thought that objections would not be allowed to plead ignorance of this very important subject much longer. It was not the egg but the sperm which determined the sex but any abnormality affecting the egg would upset the sex-determining mechanism.

## UTERINE FIBROIDS AFTER THE MENOPAUSE

BY

W. FLETCHER SHAW, M.D.

Professor of Clinical Obstetric and Gynaecology, Manchester University, Honorary Gynaecological Surgeon, Manchester, Royal Infirmary, Honorary Surgeon for Women, St. Mary's Hospital, Manchester.

UTERINE fibroids may give rise to symptoms over a wide range of age, but in practice we find that a very large proportion of patients consult us for the first time between the ages of 45 and 50, and if we advise an operation the first inquiry of the patient is the possibility of an early menopause with the probability of cessation of symptoms. Naturally every patient wishes to avoid an operation and every right-minded surgeon wishes to save her this ordeal but he is expected to advocate the best method of treatment and, in giving this opinion, he must not allow his judgement to be unduly biased by sentiment. In deciding, for or against operation two important considerations must be borne in mind: first the fact that with uterine fibroids the menopause is frequently delayed and secondly the possibility of malignant and degenerative changes occurring in the fibroids after the menopause. It is the second consideration with which I wish specially to deal.

The more experience I obtain in my work the more impressed am I with the serious complications which may occur in connexion with these tumours after the menopause. It is impossible to calculate the percentage of fibroid after the menopause which undergo serious changes, since we only see those patients in whom the fibroid is giving trouble, but even if the percentage is small we must give due weight to the fact that the removal of fibroids in a comparatively healthy woman before the age of 50 presents a very slight risk, whereas the same operation in a patient over 60 or still more over 70 years of age for a fibroid which has undergone degenerative changes from which the patient's general health has suffered is a very much more serious matter. My own belief is that a patient with a fibroid of moderate or large size will yet more wisely in getting rid of it while in a good state of health than in running the risk of serious trouble developing at a later stage of life.

During the last six and a half years I have operated upon 62 patients for definite symptoms due to uterine fibroids after the menopause, and should have operated upon three others if their general condition would have permitted it. It is upon these 65 cases that I base this paper. During this same period I have been consulted by several patients in whom the fibroid was so small and the symptoms so slight that I have advised against operation; these cases are not considered. The majority of these 65 patients were between the ages of 50 and 60, but 8 were between 60 and 70 years of age, and 3 were over 70. In several instances patients complained of two symptoms either of which was sufficiently severe to call for operation, so in discussing these symptoms separately these patients will appear in both sections.

#### General III Health. Patient not Fit for Operation

There were three patients whose general health precluded the possibility of operation. One was 60 years of age with recent haemorrhage from the tumour but she had had a recent stroke and even if the tumour proved to be malignant I did not feel justified in subjecting her to any operation. The second was also 60 years of age and had severe pain in the lower abdomen, apparently arising from a uterine fibroid but she was in a very feeble state of health with mitral regurgitation and was not fit for an abdominal section. The third was an enfeebled woman aged 72 with a fibroid almost filling the pelvis and with a slight degree of prolapse. Many years previously she was told she had a fibroid, but was advised not to have it removed. With advancing years the tumour dropped in on the pelvis and produced more and more discomfort from pressure symptoms and now she is a confirmed invalid spending most of her life in bed or on the couch and

though possessed of all that wealth can give her, she drags out a miserable existence. Here, again, her general health precludes all possibility of operation, but if this had been performed twenty years ago she would now have been a healthy old lady, enjoying life, and a source of much greater happiness to herself and her family.

### Malignancy

There is considerable divergence of opinion about the incidence of malignant disease in uterine fibroids, but I think all will agree that a uterus which contains fibroids is much more likely to undergo malignant changes than one which is free from these tumours. I am convinced that the risk of this occurring in a fibroid uterus after the menopause is to be borne in mind when deciding for or against operation. In this series of 65 cases 6 had definite malignant changes in the uterus—3 sarcoma and 3 adenocarcinoma. Their ages varied from 49 to 56 years, and they had all passed the menopause several years.

The patient aged 49 years had an interesting history. Double oophorectomy was performed six years previously for haemorrhage due to a fibroid uterus, she was brought to me on account of recurrent haemorrhages and a thin watery discharge of almost one year's duration after five years' amenorrhoea. I found the cervix dilated by what I thought to be a fibroid polypus. I performed a panhysterectomy and found the fibroid polypus to be a sarcoma. The patient died of recurrence about four months later.

Sarcoma of uterine fibroids occurs much less frequently than does carcinoma of the body or cervix in uterus with fibroids, and it is curious to find in this small series that the two types of growth were present in equal numbers. If I investigated the figures over a longer period of years I am sure the proportion would be different.

### Haemorrhage after the Menopause without Malignant Changes

This is by far the commonest symptom, and in this series 24 complained of bleeding which commenced some time after the menopause, in 6 cases this was associated with other symptoms, which are mentioned in succeeding paragraphs. These patients varied in age from 47 to 68 years. The usual history was simply recommencement of bleeding after a number of years of amenorrhoea, and, as the only physical sign was enlargement of the uterine body with the fibroid, it was impossible to say whether that fibroid was undergoing malignant change or not, unless the patient was anesthetized and a diagnostic curetting was performed. In these cases I do not think that this would be good treatment, since an early adenocarcinoma is easily overlooked, while a sarcoma cannot usually be detected, moreover, a uterine fibroid which becomes active after the menopause, and produces haemorrhage, is not likely to be benefited by curetting, and is much better removed.

### Acute Pain

Nine patients complained of acute pain in the lower abdomen, in two this was associated with haemorrhage and in one with rapid enlargement. All these tumours showed advanced degenerative changes, two with red degeneration, while two had a subperitoneal fibroid with twisted pedicle. In each case the pain was acute and led for early operation.

### Chronic Pain

Some patients complained chiefly of this symptom, principally in the lower abdomen and back, and, in some cases, radiating down into the leg. These patients, on the average, were older than those in the preceding group, in the majority of cases, no doubt, the fibroid had diminished in size since the menopause, and was producing symptoms by pressure inside the pelvis. Three of these patients complained of other symptoms in addition to this chronic pain, but in all this symptom was of such severity that they desired operative treatment, even though one was 72 years of age.

### Torsion of the Uterus

This is a very rare complication, but by a curious coincidence I have had two cases within six months, and

it is worth giving a short note of each as they are different types of onset, one acute, the other sub acute.

The first patient, an unmarried woman aged 70 passed the menopause when she was 56 and was told before that she had a fibroid, but was advised not to have it removed. Sixteen months there had been recurrent attacks of abdominal pain with sickness, and on this occasion she consulted a doctor, who found a hard, tender tumour, which the patient had increased in size. This tumour extended up to the umbilicus and was so tender that I made a diagnosis of red degeneration. On opening the abdomen I found the uterus contained an intraligamentary fibroid at the fundus, about the size of a foetal head and twisted round in two complete circles at the level of the internal os, where they were attached to the cervix by a pedicle no thicker than my first finger. The uterus, tumour, and appendages were deep purple, almost black, in colour, and were easily removed by cutting through this small pedicle. In spite of her age and the severity of the condition the patient made an uninterrupted recovery.

This is a curious case, as there was no history of acute onset, merely recurrent attacks of abdominal pain and sickness extending over sixteen months, and this last attack was little if any more severe than her previous attacks from which she had recovered.

The second patient, also unmarried, was 56 years of age and had passed the menopause two years previously. When I saw her there had been severe abdominal pain for two days which was made much worse by her journey to see me, she was so ill that I sent her at once into a nursing home. As in the last case this patient had a hard, tender mass arising from the pelvis to the level of the umbilicus, and I found when the abdomen was opened that she also had a single intraligamentary fibroid the size of a foetal head, developed in the fundus. The uterus, fibroid, broad ligaments, and tubes were greatly distended and almost black in colour, they were twisted round in one complete circle at the level of the internal os. The tumour was easily removed, and the patient made an uninterrupted recovery.

### Torsion of the Pedicle of Subperitoneal Fibroids

Two patients, one aged 53, the other 54, were operated upon several years after the menopause for acute abdominal pain due to a subperitoneal fibroid with torsion of its pedicle.

### Pressure Symptoms

Uterine fibroids, after the menopause, shrink in some cases sufficiently to allow the tumour to fall into the pelvis and so produce pressure symptoms, which may manifest themselves in various ways.

**Retention of Urine.**—Four patients suffered from acute retention of urine which had required the passage of a catheter. In all cases the fibroid was well down in the pelvis, and no doubt before the menopause it had been of sufficient size to be held above the pelvic brim.

**Pressure on Rectum.**—Two patients complained of severe rectal symptoms, which had commenced some years after the menopause, and in each case there was a uterine fibroid lying in the pelvis and pressing on the rectum.

**Bearing Down.**—Two patients complained chiefly of this symptom, though in one case there was also severe flooding. Both patients had passed the menopause several years and the symptoms had only occurred after this period. In these cases no doubt the symptoms were directly due to the post-menopausal shrinkage of the tumour, which allowed it to fall to the bottom of the pelvis.

Sometimes after the menopause the tumour increases in size, and this also may produce pressure symptoms.

**Frequent Micturition.**—Two patients complained of this symptom. In one the tumour extended almost to the sternum and was very soft, evidently undergoing degenerative changes, whilst the other was smaller in size but extended into the abdomen, and, in addition, was giving rise to muchaching, dragging pain.

**Swollen Legs.**—One patient complained of swollen legs, and had a large, soft fibroid extending up to the umbilicus which was enlarging rapidly.

### Increased Size of Tumour

Some patients had noticed recent rapid increase in size of the tumour. Several years had passed since the menopause, the increase in size was due in each case to degenerative changes of the tumour, usually cystic in nature. The rapid increase in the size of the tumour was accompanied by haemorrhage in two cases and by pain in three.

### Degeneration Followed by Infection

It is to be expected that a fibroid which has undergone degenerative changes would readily become infected, and this is a danger to keep in mind, but in this series I have only one patient who had a rise of temperature before operation. In this instance the fibroid had undergone red degeneration—a type which readily becomes infected. Probably the small incidence of this complication is due to the degeneration producing other symptoms which called for operation before the tumour had time to become infected.

### Absorption from Degenerated Fibroids

This is a very common occurrence. In this series I have three patients who were operated upon for this cause alone, though no doubt many of the other patients were suffering from absorption in addition to the more urgent symptoms which called for operation. Each of these patients suffered in general health—loss of appetite and loss of weight, and they were anæmic. All had degenerating fibroids and improved in general health after removal of these tumours.

### Ascites due to Calcareous Degeneration

This is a condition I have met with occasionally, and though it does not occur in this series should be mentioned. Occasionally in a patient with ascites there can be felt a hard tumour of pelvic origin, which is diagnosed as a malignant ovarian tumour, but proves to be a subperitoneal uterine fibroid which has undergone calcareous degeneration, and by its hardness has so irritated the peritoneum as to produce ascites.

### Tenderness after Radium

A patient aged 52, had been treated by radium two and a half years previously for hæmorrhage due to uterine fibroids. Since this treatment she had complete amenorrhoea, but complained of severe pain in three abdominal scars due to radium burns, and great tenderness in the uterus which produced severe dyspareunia. The uterine fibroid was quite small and I did not advise any operation, but I think the case should be mentioned to illustrate the fact that treatment by radium so strongly advocated by some authorities is not entirely devoid of risk.

This is my experience of post-menopausal trouble from uterine fibroids during the last six and a half years—on the average ten cases each year sufficiently severe to require operative intervention. The number may not seem very large, but when we consider the increased risk of the operation in patients of advanced age, with resistance still further reduced by changes in these tumours I do feel that this should have considerable weight with us when deciding whether a patient with a fibroid uterus before the menopause should be advised to have it removed. I give it as my considered opinion that it is much safer for a woman with a fibroid of moderate or large size (quite apart from any symptoms it may be producing at the time) to have it removed before the menopause than to run the risk of malignant or degenerative changes, which so frequently occur after the menopause.

### Discussion

Dr BETHEL SOLOMONS (Dublin) was struck by the large percentage of malignant changes in Professor Shaw's series which seemed to show that those who favoured the treatment of fibroids by x rays were acting on the wrong lines. Whereas in many cases after the menopause hysterectomy was no doubt the best operation, he thought that in isolated instances myomectomy might be preferable. He warmly advocated the use of stovaine in these cases.

Professor LOUISE McILROY (London) agreed with what had been said, she was convinced that fibroids were caused by toxæmia. She related the case of a submucous fibroid in an enfeebled patient being successfully treated by pituitary extract, quinine and castor oil, as for the induction of labour.

Professor GIBSON FITZGIBSON (Dublin) was inclined to think that some of these cases were of actual post-menopausal growth, and not necessarily changes in fibroids. It was worth remembering that many women aged from

38 to 40 might nowadays get married, and it was therefore a question whether they should postpone an operation until after the child bearing age.

Dr W. TORRICE (Edinburgh) questioned whether malignant changes were generally so common as Professor Fletcher Shaw's figures suggested. His own experience of fibroids undergoing malignant changes was so limited that the risk might almost be ignored. If malignancy was so common, then operation should be performed for small fibroids and not reserved only for large ones.

Dr J. YOUNG (Edinburgh) thought that only a very small proportion of fibroids underwent malignant changes after the menopause. He also was strongly in favour of spinal anaesthesia in old and feeble patients.

Dr J. H. FERGUSON (Edinburgh) had seen three cases of torsion of subperitoneal fibroids and three cases of torsion of the uterus itself. One of the complications of torsion was collapse from hæmorrhage.

Professor FLETCHER SHAW, in reply, expressed surprise at the unanimity of those taking part in the discussion. In regard to the occurrence of malignant degeneration in fibroids, it was a very vexed question how frequently this occurred. Statistics varied enormously. His own impression was that a fibroid uterus was much more likely to undergo malignant changes than a non-fibroid uterus. He was not so convinced that malignant change was so common that every fibroid should be removed, but he thought it warranted operation in the case of the larger fibroids. In regard to anaesthesia, he agreed that the spinal method was the most suitable unless the services of an artist in general anaesthesia were available.

## SOME POINTS IN THE TECHNIQUE OF THE LOWER SEGMENT CAESAREAN OPERATION

BETHEL SOLOMONS M.D., F.R.C.P.I.,  
Master Potunda Hospital Dublin

THE lower segment Caesarean operation is such a valuable procedure that it is necessary to bring its advantages and disadvantages constantly before the medical profession, especially in view of the fact that it is neither practised nor recommended in some of the larger hospitals which devote themselves to the teaching of students. No more illuminating argument for the advantages in the operation can be brought forward than the change in opinion of that broad minded and brilliant obstetrician Munro Kerr who in his *Operative Midwifery* (1916) stated that he believed that it would entirely disappear and be forgotten unless the caesarean in the lower segment was decidedly stronger than the one situated in the upper part of the body of the uterus. He is now well known as a strong supporter of the low segment operation.

It is necessary to discuss various points in technique as they arise, in order that some definite mode of performing the operation may be standardized to some extent.

One of the most instructive communications in recent years is the paper by Harris and Brown on the bacterial contents of the uterus. They show in this that the classical operation is the safest when performed at the time of clefion and that the bacterial content of the uterus becomes greater and advances higher the longer the woman is in labour. This might appear at first reading to be a reason for the adoption of the classical operation, but a moment's thought will dismiss this fallacious idea from the mind, for no matter in what part of the uterus the infection lies, be it high or low, it is obvious that the incision should be in the comparatively innocuous lower segment covered with bladder peritoneum rather than in the upper abdomen in close proximity to the intestines, with the likelihood of general peritonitis. These remarks apply particularly to placenta prævia. In this short series a central insertion of the placenta was

Professor McILWRAITH (Toronto) said that the lower segment operation was gaining in favour in Canada. They did not employ low section in placenta praevia or in cases where it was to be expected that the patient would go through a subsequent natural labour. He described a case in which the classical section had been performed when in a later pregnancy, rupture occurred, not through the uterine scar, but through the lower segment.

Professor HENDRY (Glasgow) welcomed the emphasis that had been laid on the opportunity for a trial labour which this operation offered. He did not think it was a good operation for placenta praevia, and he left the placenta inside as a general rule. He always used continuous catgut sutures, and had never found any necessity to drain.

Dr J H FERGUSON (Edinburgh) referred to the methods of sterilizing catgut, particularly the length of time required for each size.

Dr SOLOMONS, in reply, said that he found it difficult to say what size of catgut he used, as different makers seemed to employ different standards. Roughly speaking, the thicker the gut the longer it was left in the box. In spite of what others might say to the contrary, he would continue to drain when in doubt. His objection to leaving the placenta behind was that clots might arise when it was necessary to explore for it, and this would add enormously to the risks of the operation.

## THE UNIFICATION OF LOCAL HEALTH SERVICES.

### I—THE WORK OF A LOCAL HEALTH AUTHORITY

BY

A S M MACGREGOR, OBE, M.D., D.P.H.,  
F.R.F.P.S.G.,  
Medical Officer of Health, Glasgow

THE administration of the health services of the country is admittedly defective, and there is a general consensus of opinion that the time for unification is becoming ripe, although the precise method of accomplishing this and the difficulties surrounding it are still subjects of controversy. The defects which are to-day under criticism are very largely the product of the historical evolution of local government. The tendency of administration hitherto has been to create from time to time special local bodies responsible for the conduct of particular services wherever these could be organized as separately functioning independent units. It is not necessary to enter into the reasons for this multiplicity of services and the hesitancy to face the problems of unification. Modern ideas are causing the whole complicated structure to be regarded as, somewhat of an anachronism. The essentials of successful administration of the health services are now perceived to lie more in the direction of interdependence than of independence, and the phraseology in common use includes the terms co-ordination and co-operation, if not actual unification.

The various administrative bodies concerned in the treatment and prevention of disease now find themselves exposed to the atmosphere of modern thought. Their continued separation and isolation are becoming more and more subject to criticism. The nature of the functions they perform can no longer be regarded as falling into watertight compartments. A rigid separation between curative and preventive medicine can no longer be maintained as a working proposition.

The confusion has been still further augmented by the rapidly increasing responsibilities thrown upon local public health administration in recent years. Public health laws and regulations have followed one another in breathless haste, and bodies created for simple purposes now find them-

selves endowed with immense and complicated statutory functions. While larger local authorities have been able to absorb and apply these measures, the rapid growth in the scope of health services has raised acutely the question of the power of small authorities (apart altogether from considerations of expediency) to function efficiently, and many have indeed passed beyond this stage. It is quite clear and is recognized that efficiency, at least as regards major services, is proportional to the size of the area administered, its population, and its taxable value. This question of the size of the unit of administration lies at the root of the problem and is one of the reasons which have caused the whole structure of local government—its merits and demerits—to be reviewed in recent years from many angles. The determination of what is to be regarded as a suitable unit for local administration is a difficult but fundamental problem. The anomalies connected with the health services have become most apparent, and have helped to point the moral.

A brief summary may be given of the conceptions which have occurred to various reformers as contained in the results of the inquiries which have been conducted by the Local Government Board, the Government. All have recommended unification more or less strongly.

The Local Government Committee, known as the MacLellan Committee, 1918, recommended the abolition of the Poor Law and the merging of its functions in those of local authorities. It appears to be the declared intention of the Government to introduce a bill to give effect to this proposal. From the public health standpoint this would mean that the medical functions of the local authorities and the Poor Law authority would completely coalesce. It is interesting to observe the views then held by the late Sir Robert Morant, at that time permanent secretary to the Local Government Board. Looking far beyond the terms of reference to this committee, he signed the report on the following assumptions:

"I assume that before transference takes place the necessary extension by Parliament and by the Government departments of the various Acts and arrangements relating to the health of the people shall have been completed, on broad comprehensive lines, for securing the provision in all localities of public services, designed to prevent at least as much as to cure or to mitigate, all forms of ill health and disease, such various functions, where they are shared between two local bodies to be exercised by them in the closest organic co-operation with one another by interlocking representation of each on the other and by dovetailed schemes of work."

The Royal Commission on National Health Insurance, with commendable courage, recommended that "Insurance Committees be abolished and their powers and duties transferred to appropriate local authorities." This proposal would, if carried into effect, do more than fulfil their other recommendations, that the continually expanding medical services should be maintained in close relationship both with the centre and in their local administration, and that, considering any changes or developments in the insurance medical services, regard should always be had to the importance of the fullest possible co-ordination with other health services. The preamble to the Insurance Act of 1911 states that it is an Act for the prevention and cure of disease, and regarding maternity benefit from this point of view, it is clear that a sound insurance scheme should concern itself with the introduction of competent midwives into the homes of the beneficiaries, if it is to be truly preventive. But a service of this kind is a function of the local authority, and it is obviously anomalous that the former should be endeavouring to cover the whole ground. The former is dealing with the problem partially and imperfectly. No doubt such considerations led the Commission to say that the service element should be administered by the local health authorities.

The Consultative Council on Medical and Allied Services in England (1920) proposed a comprehensive scheme for the systematized application of medical and allied services which need not be given in detail. In the report which followed remarks occur: "Preventive and curative medicine cannot be separated on any sound principle." "The organization of preventive medicine has been insufficient because it fails to bring the advantages of the knowledge adequately within reach of the people." The Welsh Consultative Council (1920) propounded a similar

\* A paper read in the Section of Preventive Medicine at the Annual Meeting of the British Medical Association at Edinburgh in opening a discussion entitled "Should all public health administration be concentrated under a single department and the immediate control in each executive area be vested in a single individual?"

similar scheme which embodied the following "The Council have no hesitation in recommending that the future provision for the health of the people in Wales should be approached from the preventive side." The proposals contained in the reports amounted to complete reconstruction from the foundation. They were both iconoclastic and reconstructive. They made no attempt to pour new wine into old bottles feeling no doubt, that the old bottles were only fit for the scrap-heap. It is very doubtful whether legislation is likely to proceed in this country along such drastic lines. For our purposes, however, it is important to note the view that all curative and preventive, should be brought together in close co-ordination under a single health authority for each area.

As regards Scotland, the first recommendation of the Consultative Council (1920) was "Unification of the various local authorities concerned with health is urgently necessary as the next step on the way to the systematic organization of medical services throughout the country." Their second recommendation was "A complete and adequate medical service should be brought within the reach of every member of the community"—a view which led them to the logical conclusion that "medical benefit should be extended to dependants of insured persons," so as to secure a sound foundation on which to erect a complete medical service.

Recognizing that the application of convictions, however sound, would require to be brought into line with the scope and problems of local government, the Scottish Board of Health appointed a Consultative Council on a Reformed Local Authority for Health and Public Assistance which reported in 1923, having investigated the problem of local government in great detail. The difficulties of and the need for reform were succinctly expressed as follows:

(a) The overlapping and waste due to the distribution of the local administration of the health services among several different authorities in each area and (b) the fact that many of the administrative units are too small to carry out efficiently the powers and duties laid upon them by Parliament.

While town councils, county councils and district committees carry on the general public health services in their areas, other authorities administer in the same areas special health services for particular sections of the population. For instance, the Insurance Committee for insured persons, the education authority for school children, the Poor Law authority, the District Board of Control for the insane and mentally defective poor, and the local War Pensions Committee for disabled ex-service men. The two main recommendations of the Council were:

(1) The concentration of all health service in one local authority, if possible for each area, should be the immediate aim of reform, and (2) the unit of administration should be as far as possible consistent with the Scottish system of local government.

After much discussion and without complete unanimity, a unit for local health administration was fixed on the basis of a population of 50,000 persons. The report points out that there are in Scotland 201 autonomous burghs, 19 of which have populations under 1,000, 108 between 1,000 and 5,000, 57 between 5,000 and 25,000, and 17 with populations over 25,000 persons. It is clear that the smaller the burgh the more top-heavy becomes the administration of public health which includes such functions as housing and town planning, control of infectious diseases, including tuberculosis—maternity and child welfare, etc. One of the chief criticisms is that they are unable to appoint fully qualified officers and to provide the necessary institutions.

Contiguous to Glasgow there is a small burgh of 25,000 inhabitants depending for its major public health services on the adjacent city which undertakes the treatment of its infectious diseases. It would be foolish for this local authority to provide itself at this time of day with institutional accommodation. We need not, however, pursue the question of the appropriate administrative size of communities or consider the vigour with which objections are being urged such as doing nothing to offend the growing spirit of local government which unfortunately often takes the form of pride rather than of expediency.

It is, however, becoming clear that for certain special purposes large areas of administration are advisable. The

term "regional administration" is now a current one, such as is contemplated in the Electricity Supply Acts. Mr. I. G. Gibbon refers to the Merseyside Municipal Co-ordination Committee which has been formed by the towns of Liverpool, Birkenhead, Wallasey, and Bootle to provide for common action in some of their problems. Many public health problems could be dealt with similarly, for instance, hospital provision, housing, and town planning, smoke abatement and other matters.

Regional consultation and co-operation is at any rate becoming more and more a factor likely to enhance efficiency. As recent illustrations, I might quote the arrangement reached with certain other local authorities in the neighbourhood of the city, whereby gonorrhoeal ophthalmia and puerperal fever are treated in Glasgow institutions. Both of these afflictions require skilled attention and although in the latter case it may be difficult to set aside the necessary accommodation the principle involved is an eminently sound one. In a similar way orthopaedic work requires a still more involved co-operative system. The treatment of non-pulmonary, or, as it is called, surgical tuberculosis is best carried out in a large and well equipped institution. Similar considerations apply to the management of the late results of encephalitis lethargica. I have mentioned these points because they are essential to the efficient solution of the growing complexities of public administration.

The question of unification of local medical services may be looked at in the light of the principles underlying the preventive work of a local authority. This has grown up out of small beginnings, the first and sole function being the suppression of nuisances, just as the huge Poor Law system in its modern form grew up out of Poor Law relief. In the course of time there appeared other bodies endowed with medical functions. In this hierarchy of local administration the local authority is now the principal vehicle of health administration especially on the preventive side. It selects for attention an increasing large number of diseases, again, which administrative measures can have some hope of success, or where, as in the case of pneumonia, measles, and whooping cough, prompt institutional or other treatment is likely to reduce the consequences to the individual. It administers a large group of laws and regulations dealing with environment. Further, in its maternity and child welfare schemes it selects certain groups of the population for preventive attention, connoted by the term "welfare," a word which quite suitably expresses the modern conception of its functions.

The work of a local authority as regards disease has three guiding principles: (a) it selects particular afflictions, or even stages of an affection where prompt and suitable treatment may avert consequences to the community or to the individual; (b) the completeness with which a preventive field once selected is covered is an element in successful administration; (c) the study of environment in relation to disease is one of its prime functions.

No other local body fulfils these functions. The Poor Law authorities in some places—notably in Glasgow—are animated by high ideals. They have found by experience that it pays them to provide the very best treatment for the sick poor at the very earliest stages of their illness. It is one of the criticisms of the Poor Law that so few authorities have realized this. In practice, however, we find that the local authority and the Poor Law authority deal with the same diseases or with different aspects of the same disease. We may even find an ambulance of the local authority removing a patient with pneumonia, and shortly afterwards one from the Poor Law authority removing a patient with pleurisy from the same address. Although there exists very close co-operation the situation is full of anomalies and it is more than probable that the total institutional accommodation available in Glasgow—some 5,000 beds belonging to both authorities—could be distributed to better advantage during times of epidemic pressure, were they under unified control.

As regards the medical side of education authorities, here again preventive work reaches a high level; but this remedial work could quite well be extended to children under school age. The more the work of a local authority in its child welfare schemes reaches the child of school age,

the more difficult it is to find any rational basis for separation of function as between the two bodies. A very practical point emerges here. The remedial and preventive work of the local authority and the education authority are so closely dovetailed that the multiplication of clinics by the respective authorities for their own purposes is likely to lead to chaos and extravagance. To mention only one point, the provision by both authorities of dental or ophthalmic or orthopaedic treatment in separate buildings with separate administration, for the same area, is clearly unsound. The question of acute rheumatism and rheumatic heart disease in children is at present receiving much attention, and I confess to being in considerable doubt as to what precisely might be the respective functions of the two authorities when a complete scheme comes to be evolved.

The Insurance Act is an Act for the prevention and treatment of disease, and I have already mentioned the recommendation of the Insurance Commission that Insurance Committees should be abolished and their functions transferred to local authorities.

The modern tendency to separate diseases into compartments or specialties in separate institutions is giving rise to much complexity. The same remark applies even more forcibly to the multiplication of clinics for a variety of purposes. It has been found to be administratively convenient to provide clinics for tuberculosis, child welfare, and venereal disease. Remedial clinics for various other purposes are being suggested, while the general and special hospitals have their outdoor departments, as have also the Poor Law authorities on a smaller scale.

I feel quite certain that it will be left to someone some day to bring order out of confusion, and that in each appropriate area there will be established what may be called a health centre, within the walls of which will be combined facilities for the examination and treatment of all patients who may be referred to it for appropriate advice by the medical practitioners in the neighbourhood. The scope of such a centre can be only partially visualized at the moment, because a complete scheme of this kind, to be associated with a really preventive service in which the community and the medical practitioners of the areas could take part, presupposes the extension of medical benefit to dependents, and the unification of all public bodies engaging in medical work under one authority. There would thus remain the public health authority on the one hand, and the voluntary institutions on the other, both co-operating in a common cause. At present we are only partially organized for the proper application of preventive medicine in its best sense.

The whole essence of preventive medicine as applied to the community is the removal of conditions prejudicial to health, whatever these may be—from removal of nuisances to the provision of houses, and from the destruction of rats to a smokeless atmosphere, as applied to the individual it means the prompt detection and appropriate treatment of defects or diseases, it also implies the maintenance of the health of the individual with his active co-operation, assisted by a knowledge of the laws of health and hygiene. Now this covers a great deal of ground—indeed, the whole province of medicine as applied to the community. Every physician, every volunteer or official body concerned with health, is working within this ground. Preventive and curative medicine are thus proceeding hand-in-hand. The loom of medical science is busy weaving them together, and they will some day emerge completely interwoven without any tears or gaps in the fabric.

## II—THE FACTORY MEDICAL SERVICE

BY

E. L. COLLIS, M.D., M.R.C.P.,  
Mansel Talbot Professor of Preventive Medicine, University of Wales

THE question for discussion, so far as the factory medical service is concerned, is one of immediate practical politics—more so, probably, than for other public health services. Our code of factory legislation has grown up distinct from other public health Acts, and claims an ancestry dating from 1802. It is administered by a highly skilled

expert staff of inspectors, the great majority of whom are not medically qualified. This staff has always formed part of the Home Office, but a transfer to the Ministry of Health would be merely a matter of central office allocation and would not in any way alter the present direct factory inspection from Whitehall.

This method of administrative control has been copied in Acts concerned with mines, alkali works, explosive factories and vivisection—wherever, indeed, technical knowledge is needed over and beyond what may be reasonably acquired in each executive area. It differs essentially from that of the Public Health Acts, which are administered by local executive authorities, advised and assisted, rather than coerced, from Whitehall. Here, however, such problems as those connected with water supply, housing, refuse disposal, and school medical inspection are common to each executive area, and knowledge concerning them may reasonably be acquired in each area.

This difference, however, does not necessarily run counter to the suggestion that locally one single person might control the factory medical service as well as other health services. This suggested control might interlock with an inspectorate centrally controlled, the advantages or disadvantages of the plan must depend on what is meant by factory medical service, now and in the future.

Apart from the cost of the Factory Inspection Department of the Home Office, the cost of all health provision in factories regarding such things as sanitation, cleanliness, overcrowding, ventilation, drainage, lighting, first aid equipment, cloakrooms, washing facilities, canteens, medical examination of young persons, and the like, is a charge on each particular factory. Each factory is a separate unit within an executive health area, and pays rates to the health authority of that area. The activities of the area health department are financed from the rates, they benefit the whole of the area.

A reason for giving special thought to day to factory health service is that there is before Parliament a bill for consolidating factory legislation. Such a bill was introduced in 1924 by the Labour Government. In a modified form it has again been introduced by the present Government. The sections concerned with industrial medical service, except for slight differences in drafting, contain the same provisions in both bills, they may, therefore, be regarded as non-controversial.

The provisions in the present bill indicate the scope contemplated for factory medical service. Hence some conclusions may be arrived at as to whether this service should in each executive area be vested in the immediate control of a single individual who also controls municipal, school, and all other public health administration. When considering the provisions of the bill medical service only will be reviewed, although the whole bill may rightly be envisaged as a public health measure.

The first medical provision (sec. 64) is a new one. It confers on the Secretary of State powers to make orders for special medical supervision. The occupier, in order to secure the health of the persons employed, may be required to make reasonable provision by arrangements for the special medical supervision of the workers. The precise way in which this new section will work can hardly be foretold until an order has been made under the proposed powers, but we note that the section contemplates the occupier himself making the provision, not the provision being made for him by some outside authority.

The next medical provisions are concerned with the duties of "appointed doctors," as the certifying factory surgeon of previous Factory Acts and of the Workmen's Compensation Act is now to be called. "Appointed doctor" is defined (sec. 132) to mean a medical practitioner duly appointed to act, and the Secretary of State or chief inspector may appoint (sec. 112) a sufficient number of duly qualified medical practitioners to be appointed doctors for the purposes of the Act, and may revoke any such appointment. The fees to be paid to appointed doctors for carrying out their duties are determined by the Secretary of State (sec. 113), and may be paid by the occupier if the duties concern the examination of young persons, or medical examination of workers by regulations made under the Act.

Appointed doctors may be called upon (sec 64) as heretofore to investigate special cases of death, injury, or disease, but duties under this section have in the past been unimportant. The main duties, as of old, will be concerned (sec 86) with the certification of young persons under 16 years of age for factory employment. Here the section contains a new plan in subsection (4) which runs as follows:

The Secretary of State may, after consultation with the Ministry of Health by order in force to the county council the duty of arranging for the medical examination and certification of young persons under the age of 16 years under this section.

This provision clearly contemplates the local health authority carrying out the duties of appointed doctors. The advisability of such action will be considered later. A further new enactment [sec 86 (6)] in this connection is that every local education authority must produce to an appointed doctor, for his confidential information so much of the school medical record of a young person as may be necessary to enable him to carry out effectively his examination previous to certification. There can be no doubt about the wisdom of this provision.

When the post of appointed doctor, as just outlined, is compared with that of certifying factory surgeon as it at present exists, the posts at first sight seem identical, and there does not appear to be any justification for altering the name which has existed since 1844. Yet the alteration in name cannot be merely the fancy of a drafting clerk. It challenges attention. We find that under codes of regulations applied to certain dangerous trades there have for long existed "appointed surgeons." These doctors, who might or might not be the certifying factory surgeons of the district have been chosen by the factory to carry out duties required by the regulations and have been submitted for approval to the chief inspector of factories who has then appointed them to act.

The work done by these appointed surgeons has always been recognized by the Factory Department to be good; not infrequently employers have extended the duties of the office to wider supervision of health matters than those embodied in the regulations under which the post of appointed doctor has been created. The thought arises then that the change of name may contemplate extending this type of appointment in place of appointments made, as now, for whole districts—appointments in which the factories have little to say but are compelled to accept and to pay. There is nothing in the bill against such contemplated action and action on such lines may prove to be the foundation of a real factory medical service.

Legislation as just outlined it is true does not contemplate a full and wide medical service; it does not stand in its way but it only provides for the prevention of ill being among workers. As usual legislation must not be expected to proceed ahead of progress; it can only register good custom and consolidate ground gained. It is a bulwark against backsliding, not a spearhead in advance. But there is a wider and higher factory medical service—that is, the maintenance of health. This service is of direct economic value to wage earners and to the public; it is this service the community needs and industry requires. It is in the light of maintaining such a service that the present discussion should be regarded.

In the past the office of certifying factory surgeon has not led to the evolution of a good factory medical service. What are the possibilities of such a service? The United States is exhibiting. Medical examination of all adults and young persons alike before employment, re-examination on return after sick leave, supervision of first aid and of all health hazards—in some cases even the establishment of a polyclinic to advise the home doctor (there are of course no private doctors in the United States) and the provision of rest homes in the country—a voluntary medical service with no legislative enforcement behind it, a service which, while it appeals to humanitarian motives, is recognized as good business. It pays; it reduces labour turnover, it lessens accidents, it minimizes sickness, it increases the quantity and quality of output. Labour is too costly and too scarce in America to be left uncared for, and this care ends in reducing costs of production.

A reason why the office of certifying factory surgeon in

the past failed to evolve on American lines may have been that a medical man was thrust upon the industry of a whole district from Whitehall, while also his fees were fixed. The doctor found his fees skimpy and tended to respond with skimpy service. Industry submitted, paid, but saw no reason to extend such service. Once each factory is allowed choice of doctor the picture should alter. In the past dismissal of a certifying factory surgeon for inadequacy has not occurred—how could a Government office dismiss its own nominee (often nominated owing to political influence)? But the office has always felt to be in a stronger position in criticizing the work of appointed surgeons and in insisting upon a high standard of work, and indeed has always obtained it.

Each factory is and should be recognized to be a unit possessing its own services for engineering management, technical production and medical supervision, all carried on in the interests of trade, just as each local authority possesses its engineers, lawyers and medical officers for conducting the business of the locality in the interests of its inhabitants.

The Ministry of Health calls for health activities, and then supervises and inspects the activities of the local authorities. The Home Office calls for compliance with the Factory Acts and then supervises and inspects the compliance accorded by each factory.

Any plan which contemplates a local authority carrying out medical services for a factory seems to be crossing the lines of efficient action. Craft the proposal to its logical conclusion and see the result. The local authority acting presumably through some extension of its school medical service would examine and certify young persons for employment for which purpose a more or less intimate acquaintance with the conditions of local industries would need to be acquired. The occupier would have no say in the medical personnel carrying out the work (which might change frequently), but would have to pay the prescribed fees and would be no more likely than at present to desire extension of such a service—and it is just this extension which is most needed. But allow that he did desire such extension on lines developing so advantageously in America, how could such service be provided by a county council through its medical staff? Either the occupier would have to engage further medical help to do the rest of the work, a plan which would cut in two and hopelessly spoil his medical service, or the county council would have to set aside whole time officers to do nothing but factory work when the only possible reason for the proposed plan—continuation of school medical service—would be lost, and the council would either be providing to the factories a useful service free or taking fees to pay for the service. But quite likely the occupier would object to paying the fees on the plea that he already through the rates is paying the salary of the medical officers concerned. If his objection were upheld he would receive a service of economic value to his business at the public expense. It would seem to be as reasonable for the county council because it employs certain engineers to insist on supplying factories with engineering service. The factories should supply their own medical service.

Maintenance of a good standard of work should certainly be ensured through inspection by which should be understood the distribution of information, help and advice, while penal and punitive action is kept in reserve. More and more is this becoming the spirit in which the factory code is administered; it has long been the spirit adopted by the Ministry of Health. A minimum medical service such as the present factory bill contemplates may be laid down by law, but industry under inspection should then be left to carry it out and develop it. So it may become as full of useful and humane activity as it is certain to be an economic proposition. The experience of the past has shown that a medical service inflicted upon industry may remain over long years futile, ineffective and incapable of full development.

# DISCUSSION

Professor F. E. WYNN (M.O.H., Sheffield) said that the proposed unification of these services was only a reversion to the findings of the Royal Commission of 1869. The

wisdom of those findings had never yet been seriously challenged, yet very little had been done in the way of adopting them practically. The Ministry of Health had been formed with a view to such unification of services, yet the health services were still administered centrally by a number of Government departments. He was convinced that there should be one Minister and one department co-ordinating all these services, and local unification and co-ordination would follow. He emphasized the importance of continuity of the health records, or "medical history sheets," of the individual from infancy, through school life, and until the advent of the insurance status. At present the records laboriously kept by different local departments were largely wasted. It was also, he thought, most important that junior medical practitioners entering the public health service should have an opportunity of studying all branches of the service. It was a bad thing for a newly qualified practitioner to be placed in a "compartment" where he saw only tuberculosis. That was not the way to learn the diagnosis of tuberculosis. He should have his fair share of clinical work in the isolation hospitals for infectious diseases, and in the maternity and child welfare and the school medical departments, with reasonable opportunities for studying general sanitation and administrative methods, including statistics and finance.

Dr J H MEIKLE (Edinburgh education authority) defined the position of the school medical service in Scotland, where the local education authority was quite separate from the county or burgh council. In some counties the local medical officer of health was also school medical officer, but this was not the case in other counties and in the larger burghs. Co-operation was, however, promoted by the issue of a memorandum in 1919. In Edinburgh there was regular interchange of information between the medical officer of health and the school medical officer. Dr Meikle thought that the school medical staff might preferably be controlled by the local education authority, and that the joint use of clinics by the two authorities would be economical.

Professor E W HOPE (University of Liverpool), in a memorandum which was read by the honorary secretary, explained how the conscientious recognition by various Government departments of their health responsibilities had led to overlapping, duplication, and expense. These departments were naturally reluctant to hand over to a central body duties which were already being efficiently discharged. Moreover, legacies of arrears of work due to the war complicated the situation further. There was still confusion in the definition of the respective scopes of operation of the authorities responsible for dealing with destitution and disease, thus the Poor Law authority was still charged with the administration of vaccination. Artificial and sectional defects minimized efficiency and increased expense. Professor Hope concluded that unification was desirable, and that one chief medical officer might well supervise and guide the activities of a staff engaged in the various administrative details directed towards the prevention of disease.

Dr F DITTMAR (Scottish Board of Health) said that of late years the large city parishes of Glasgow, Edinburgh, Aberdeen, and Dundee had established hospitals which were comparable with the large voluntary hospitals of those cities. In Glasgow those Poor Law hospitals already had their consulting staffs, medical, surgical and specialist. The time had now come when all work, both in connection with infectious diseases and general diseases, should be undertaken by the local authority responsible for the administration of public health in its area. This had already been done in Aberdeen, where the city council had, by mutual arrangement, taken over the whole of the Poor Law hospital service. The medical services of local authorities included the general administration of public health, the isolation and treatment of cases of infectious disease, and the administration and treatment of tuberculosis, maternity and child welfare, and venereal diseases. The education authority had its own medical staff, which naturally co-operated with the public health authority.

The medical officer of health, who was directly concerned with all questions affecting the health of the community, should be the head of the unified department of public health. In some cases this arrangement was already in force, but in other cases it had not been attained. Various reasons, partly financial. Many administrative difficulties could be overcome by enlarging the area of local authority. In factories the general sanitary and health conditions would naturally be under the general supervision of the medical officer of health, but special medical welfare work should be controlled by the factory concerned. It had already been demonstrated in the United States that such work was in the interests of both employers and employed.

Dr F N K MENZIES (MOH and school medical officer, London County Council) explained the present system of administration of public health in the London area. From this point of view, he said, there were many "Londons." There was the area of the administrative county, the City of London, water London, the Port of London, and twenty-eight metropolitan boroughs, varying in population from 50,000 to 350,000. In addition to these there were the various Poor Law authorities with different boundaries, and the Metropolitan Asylums Board. All these authorities were performing their different but often overlapping functions. The result was a remarkable example of apparent administrative chaos, but on the whole the scheme worked very well, although it involved overlapping, friction, unnecessary correspondence, and administrative waste. The whole problem, in his opinion, depended for its solution on finding the ideal unit of administration. Public health work had developed so much, and conditions varied so widely, especially as between urban and rural areas, that he was of opinion that each county should be left to formulate its own scheme, without any one scheme being regarded as a precedent for different areas.

Dr W F DUNN (factory surgeon and port sanitary officer, Manchester) said that if a factory prejudiced the health or comfort of a community by polluting the atmosphere, or rivers, or sewers in the neighbourhood, the community should have the right to interfere. But the processes in the factory itself were not the concern of the community as such. Such conditions must be regulated by the industry itself and not by the local authority. Already any industry which endangered the workers was governed by regulations which were drafted after consultation between representatives of the employers, the workers, and the Home Office. The administration of such regulations could not be undertaken by local authorities, certainly not with any hope of uniformity of action.

Dr J MIDDISTON MARTIN (county medical officer, Gloucestershire) gave as an illustration of the confusion that had arisen in public health administration cases in which a local authority had certain duties to perform in connexion with elementary schools and maternity and child welfare work, while the secondary schools and other branches of maternity work, including the supervision of midwives, were under the county council. The hope of those interested in the co-ordination of these services had been raised by the proposals of the Minister of Health with regard to the rearrangement of the Poor Law medical services, but those hopes had been dashed by the announcement of the present watered down proposals. He was convinced of the fundamental necessity of there being one authority with one administrative head for all the health services of a community.

Dr J P KISTOCH (MOH, Aberdeen) explained the arrangements under which the City Council of Aberdeen had been enabled to take over the whole of the Poor Law hospital service, thus bringing about a real unification of public health services. He did not agree that there was any good ground for the divorce of factory health from factory medical inspection from other departmental functions of hygiene, and he believed that in the future the factory inspector and the sanitary inspector should be

will be combined. Discussing the size of the unit of health administration, he said this might easily be made too large. Perfect co-operation could be arranged between a central city with highly equipped hospitals and medical experts and the surrounding county units—a form of co-operation which it should be the duty of the Government to encourage.

Dr H S BEABLE (Romford), representing the Pool Law Commission Committee of the Association, stated that unification and not merely co-ordination of all health services was already the settled policy of the Association, but such unification must begin at the centre—the Coventry and departments concerned, and local health committees must not be the committees as now known. They must be strengthened by the co-optation of representatives of the medical profession nominated by the local practitioners on the lines of the present Insurance Committees, with an Advisory Medical Committee.

Dr H SCARFIELD (late M.O.H. Sheffield) favoured experiments in the direction of unification by means of co-operation as had already been done in Aberdeen, Gloucestershire, Essex, and Cardiff, so as to relieve a single public medical and nursing service with the consequent saving of time and money. He agreed with Professor Collis that the factory health service was a special one and advocated closer co-operation between this service and the local public health department.

Dr D McKAIL (Glasgow) expressed the view that all the confusion that had arisen was the result of ignoring the general practitioner. He thought that no one should be admitted into the ranks of the public health service without

at least three years' experience of the "rough and tumble" of general practice.

Dr E H SNELL (M.O.H., Coventry) said it took the allied issues during the great war some three years to discover that success could only be achieved under a unified command. When the public health service learned the same lesson it would achieve the same result.

Dr W A LETHBRIDGE (Ministry of Health) emphasized the necessity of a general training in public health work of junior members of the service. The need for this would be increased by any further unification of such services. Difficulties had already been experienced in certain towns on the retirement of the chief official when it had been found that the subordinates, who were familiar only with the work of one subdepartment, were not qualified to take his place. As the scope of preventive medicine widened it would become increasingly difficult to find men capable of looking upon public health work as a whole, unless an effort was made to train the junior members of the personnel.

Dr A S M MACGREGOR, in a brief reply said he thought there was no doubt that the balance of opinion had been in favour of unification. He was himself convinced that some form of amalgamation of existing services was necessary and inevitable but he could not agree that the factories should be included in any such scheme. In Glasgow a number of factories had already made their own provision for health services and he was satisfied that this was the right line of development. He believed that the only alternative to a State medical service was "general practice" on a higher plane than had been known in the past.

## GROWTH IN ITS PATHOLOGICAL RELATIONS \*

BY

ARCHIBALD LEITCH, M.D.

Director of the Cancer Hospital Research Institute

THE cells of the body having attained during foetal life their destined characteristics of form and function, according to those of the organs of which they form component parts, lose to a varying degree their powers of reproduction. Some tissue cells have lost that power before birth, some retain it as long as life lasts, but in general the earlier the time at which complete differentiation of form and specialization of function have occurred, the less these powers can afterwards be displayed. At no time can we say that any normal cell however undifferentiated, has an unlimited potentiality of proliferation; its bounds and its destiny are set before it by natural factors, of which we have only the vaguest and most imperfect notions. From its behaviour in normal circumstances we are not entitled to assume that it had more than rigidly restricted powers of reproduction but by our observations of the phenomena of repair we can be certain that some cells at least have a hidden reserve of power and by cultivating normal tissue cells in suitable nutritive media outside of the body we can demonstrate that they are actually endowed with limitless reproductive powers which, in whatever way they are controlled are not exhibited in the living composite organism. Not every kind of tissue cell has been cultivated so far but since we have succeeded in growing such early and severely specialized cells as those of cardiac muscle and have seen these cells exhibit their characteristic physiological property of rhythmic contraction we may safely assume that all kinds of tissue cells have this potentiality. This autonomy is not lawless; each kind gives birth only to cells of the same class and characters they remain in close communion with each other; they tend to arrange themselves in the pattern that prevailed in the organ from which their ancestors were removed but when such a colony accustomed for many generations to its independence is returned to the animal

body the unrestricted power vanishes at once. It has been claimed that by employing certain agents which we have used to induce malignant change in body cells, the cultivated cells can so be affected that their reproductive powers will not be restrained even in the environment of the living body but the claim has not been corroborated. However that be it is now beyond doubt that tissue cells have inherent powers of limitless growth, and that these powers are kept in check by some inhibitory factor in the body.

Throughout life in normal physiological conditions we have tissue cells that are constantly being lost and replaced and others that in post-foetal existence remain constant fixed in number, and irreplaceable. The squamous epithelium of the surface and of cavities in communication with it, and the glandular epithelium of the intestinal tube, as well as of certain gland structures are examples of the former whilst ganglionic nerve cells serve as a good example of the other extreme. It is true that cells of the former class are quite highly differentiated in form and in function, but bearing in mind that in certain conditions in adult life a glandular epithelial cell may assume the characters of a squamous epithelial cell though the converse is more doubtful, we may say that the specialization is not absolutely rigid. In physiological replacement the activity is confined to the one tissue and adjacent tissue cells do not participate nor is the replacement out of uniformity with the original plan. Whether the connective tissues are normally in this state of continual renovation, or fixed and unchanging, is a question that in the nature of things cannot be determined.

In reparative processes following loss by wounds or degenerative lesions the active proliferation of connective tissue cells is such a predominant feature that the regenerative powers of other tissue cells are for the most part masked and overwhelmed but still it may be said that the latter exhibit the property in inverse relation to the degree of their specialization. At one extreme the epithelial tissues display considerable powers of proliferative regeneration, and at the other the reproduction of such rigidly specialized cells as cardiac muscle and nerve cells is wholly suppressed. There are signs that ordinary striped muscle cells make a feeble attempt at repair, but it can hardly be claimed that they actually multiply. When the injurious

\* The opening paper of a discussion in the Section of Pathology and Bacteriology at the Annual Meeting of the British Medical Association at Edinburgh 1927.

action is repeatedly inflicted—that is, when it becomes a question of irritation—the stimulus induces an exaggerated repair, and the multiplication of cells is excessive. This hyperplasia in the ordinary course of events is temporary, as, owing to the subsequent maturation of the connective tissue cells, with the consequent devascularization, a shrinkage to or below the original limit occurs. That the proliferation of cells should cease when the defect is made good is no less mysterious to us than that they should commence to multiply to fill the gap. In the same process are exhibited the inherent capacity of cells to multiply and the restraint exerted upon them when the original plan has been restored. Sometimes the inhibition is late in coming into operation, as in the case of keloid formation, but the phenomenon of arrest is always evident. As we pass to tumour formations the less do we see exerted this repression of an inherent power in the cells, until in the extreme degree of malignancy the restraint on cell proliferation is almost entirely removed.

The boundaries between reparative growth, hyperplasia, and neoplasia are impossible to define—in fact, a tumour is a localized hyperplasia, nor is there any strict separation possible between benign and malignant growths as a whole. The words "benign" and "malignant" are clinical terms, and though they can often be related to histological appearances in tumours, yet the relationship is by no means invariably close. The gradation of the various processes suggests a difference of degree rather than any qualitative distinction, in short, the cell in neoplasia acquires no altogether new capacity compared with the cell in reparative regeneration. It will follow from this that tumours can only arise from such cells as can regenerate, and the frequency with which cells take part in neoplastic processes will be inversely related to their degree of specialization. But at once we are confronted with the fact that tumours are found composed of cells which do not multiply in adult life. The work of Cohnheim, by laying particular stress on these exceptional tumours, and by referring all tumours to the same origin as he quite rightly attributed to them, has given them an undue prominence. If cardiac and voluntary muscle cells, ganglionic nerve cells, and cartilage cells do not regenerate in post-foetal life, we must either give up our contention or fall back on the explanation that tumours composed of these cells have arisen from them when they were still in an embryonic and less highly differentiated state. In the latter case we may imagine with Cohnheim that such cells were cut off from communion with their kind which went to form useful organs, that they lay dormant with their proper destiny thwarted and their innate powers of reproduction still preserved until such time as some unknown stimulus unloosed them.

Let us examine these disturbing tumours more closely. Cardiac muscle tumours are the rarest of all tumours, they are composed of peculiar cells which here and there display the characteristic striation in parts, they are small in size, they are accidental *post-mortem* findings, they have no malignant characters, and they are doubtless congenital. A peculiar feature of striped muscle tumours which are also pathological curiosities is that they are found mostly in situations where voluntary muscle does not normally exist, and then generally in association with other aberrant tissues, and it has been held that they originate from smooth muscle and not from striated muscle. At any rate, we have no satisfactory evidence of the formation of such tumours from adult striated muscle, and it is generally agreed that they originate from embryonic remnants. Rare, too, are tumours composed of nerve cells. Such tumours seldom show malignant characters, and they make their appearance evident at an early age. They are undoubtedly congenital. The retinal neuroma, on the other hand, which betrays its presence in early infancy, is highly malignant. Sometimes it is bilateral and sometimes unilateral. It is derived from one of the most highly specialized classes of cells in the body, but everything points to its origin before birth. These examples will serve to show that we must suppose a retention of embryonic proliferative properties to explain certain exceptional tumours, but it is easy to believe that they started as tumours when the parent cells were not rigidly specialized as that they arose in later life from

segregated cells that had lain dormant and deep. No one will deny that there are segregations of cells off in development and that they are by no means frequent, but that these isolated communities are not so different from normal adult tissues to neoplasia is open to question. Still, experiments on the production of cancer have led us to think that it is possible so to change the nature of the cells that while they may seem for a brief unaltered in microscopic appearance or in behaviour they will subsequently fling up in malignant proliferation. There is thus experimental evidence that may be adduced in support of Cohnheim's contention. The tendency to explain morbid growths is originating from embryonic faults is less pronounced now than formerly. For example, cartilage is a tissue which seldom if ever regenerates, and chondromata are not uncommon, and while we may see a developmental fault in the case of the echinoderm for the true chondromata and for the mixed cartilaginous tumours another explanation is feasible. It is probable that the connective tissue cell may form collagen or chondrocytes, or myxomatous, cartilaginous, or osseous rates in different circumstances. In pure chondromata the very frequent association of myxomatous and cartilaginous areas is very suggestive, and still more is this the case in the mixed tumours. When we reflect that a connective tissue may be found in arteries and can be produced in them experimentally by painting the vessel with such substances as silver nitrate, and, above all, when it can be produced by the injections in rats which will stimulate the production of cartilage and bone, we have no option but to believe that the connective tissue cell is not unalterably fixed in adult life and may exhibit rather surprising metaplasia.

The reproductive power of cells, as has been said, is in inverse ratio to their degree of specialization, but this is not invariably the case. The cells of the mammary gland multiply in preparation for their most highly specialized function—lactation, and probably also in response to the stimulus of the ovarian hormone. Malignant neoplasia rarely occurs in the mammary gland, which is not highly differentiated in function. It is remarkable that when a mouse is inbred for the development of strains with a high incidence of mammary carcinoma, the spontaneous tumours occur only in the females, and if the females are sprayed during the first few months mammary tumours do not appear in them. Thus a less functionally specialized epithelium is less prone to neoplasia than one more highly developed—in exception to the general rule. What the ordinary function of the mammary gland may be is unknown. The secretion of milk is certainly a very specialized function, but, after all, it is only occasionally that it is called forth. Malignant tumours of the breast are almost as common in barren women as they are in those who have suckled children.

On the other hand, the degree of malignancy in a tumour corresponds with the degree to which the constituent cells lose their functional properties. In the intestinal tract, for example, the secretion of mucus is, though perhaps not the chief, of the functional properties of the epithelial cells, but in carcinomata arising from the cells it can be shown by appropriate staining, that the function is very greatly diminished and in extreme cases may be entirely suppressed. The instances might be multiplied, but here again there are apparent exceptions to the rule. In melanotic cancers the intense production of melanin is characteristic, and though in parts of the tumours, indeed sometimes in whole metastatic nodules, the melanin may be largely wanting and the impression of blandness may be due mainly to the crowded with the black granules is very noticeable. Despite the great amount of investigation that has been done in the chemistry of malignant cells, there has been nothing to suggest in qualitative difference between normal cells, the differences being for the most part quantitative and inconstant. While recognizing this, we may say that the exercise of the reproductive power of cells is maintained at the expense of their specialized functions. The analysis of this inherent reproductive power of cells displayed physiologically, in repair, and in the

pre-sents problems of the first magnitude to all biological sciences, and is not the province of any one alone. It would seem as if the same principle were in action in the three phenomena, the resulting reaction being determined by the extent to which some inhibiting process was at work and in the almost complete absence of definite knowledge of this growth principle the pathologist is thrown back on the study of the inhibitions, how they are removed or how they may be fortified. The older conception of which Ribbert was an exponent, was that the inhibiting factors were purely environmental: if the restraint of the environment were weakened or removed the cells of a tissue would exhibit their innate property of unceasing multiplication. It has already been mentioned that by cultivating cells in suitable media outside the body this can be demonstrated, and that if these emancipated cells be returned to the animal body the process is arrested and we might be tempted to conclude that the arresting force was exerted purely by the environment. But if the cells cultivated have been from a malignant tumour originally, the implant will go on increasing and yet the environment in both cases is identical. From the impasse into which this has led us there are two ways of escape—either to assume that malignant cells have required an entirely new property not possessed in any degree by normal, reparatory, or benign tumour cells, or that they have developed in excessive abundance an already existing property. In the former case an easy explanation would be that in the cancer cells there is an extraneous agent remaining always intracellular, which stimulates these cells to division and multiplies with them. This conception forms the basis of the parasitic theory, which has been rejuvenated by the strikingly original investigations of Gre and Burnard and still more by their daring, and perhaps somewhat risky, conclusions. If we accept the other idea we shall have to conceive of a growth substance generated by the cells capable of being stimulated to overproduction. In wound repair we may imagine that there is a transudation of growth substance in limited amount which not only stimulates the particular parenchymatous cells to reproduction but also stimulates the adjacent connective tissue. In neoplasia the stroma formation is even more essential. It is difficult to conceive any other means of local stimulus to connective tissue formation than the outpouring of some factor from the neoplastic cells. So far no one has been able to isolate this hypothetical growth substance, and the evidence for its existence is indirect and of doubtful validity. As is well known animals may be 'immunized' against transplanted cancer by previous treatment with red blood corpuscles, spleen tissue and other unskilled tissues of the same species and the only difference that can be detected in the phenomena that follow the inoculation of grafts in the refractory and the control animal is that in the former no stroma formation is evoked. Although it is impossible to find in the refractory animals any of the known serum antibodies, we may imagine that the immunizing treatment has induced the formation of an antagonistic substance which neutralizes the growth substance poured out by the cancerous cells. There is another experimental observation which supports the notion of the outpouring of growth substance. In the transplantation of certain strains of mammary carcinoma in mice and rats sarcomatous transformation of the stroma tends to occur. In ordinary cases the stroma introduced along with the parenchyma in grafts always dies and is replaced by new stroma furnished by the new host but in these cases the stroma continues to proliferate. That the implication of epithelium of the same kind adjacent to a carcinoma is due to the same thing is much more dubious. But when all is said, we must confess that we have no explanation of the unceasing transmission of the acquired property from cell to daughter cell. That growth may be temporarily arrested in malignant neoplasia even for long years is certain but the cells so arrested do not lose their power. Heiman of the Crocker Research Laboratory has implanted a very active carcinoma into the midst of a slow growing transplantable fibroma of the rat, and in this fibrous prison the carcinoma lives but does not increase but if it is set free from its bonds, by the cutting up of

the composite tumour or by transplantation into a new host, it demonstrates its malignancy. Here the proliferation is quite arrested it may be for long periods but the malignant potentiality of the cells are not destroyed. Must we, then, conclude that there is a fundamental difference between the normal and the cancerous cell, and that the latter possesses some property quite foreign to the other, something extraneous? It is tempting to seek rest for our puzzled minds in such a belief, but when we face the fact that we can induce cells to become malignant by the use of certain carcinogenic agents long administered, and more especially the fact that we can biologically affect cells so that after a long period of normal quiescence they will break forth into malignant proliferation we must reconcile ourselves to the troubled doubts that may lead us to clearer knowledge.

#### DISCUSSION

Professor R. Mcm (Glasgow) said that the cellular proliferation underlying pathological growth constituted a fundamental question. No real explanation of it could be given at present little more could be done than to analyse and classify the factors concerned in its occurrence. Apart from tumour growth, cellular proliferation was recognized to result (1) from breach of continuity, (2) from irritation, and (3) in the case of certain tissues, from excessive functional demands, cellular hypertrophy being followed by hyperplasia. Each of these must be further analysed. But there were other examples of proliferation which could not be placed under these headings, as, for example, the regenerative proliferation of erythroblasts after haemorrhage and the proliferation of myelocytes in leucocytosis. The question as to what extent definite substances acted as stimuli to proliferation was very important. The excessive growth of certain tissues in hypophyseal superactivity was a well recognized example of such an occurrence, but in connexion with tissue culture it had become a practice to speak of growth promoting substances, stimuli, or trophics, and to explain the proliferation as the result of their action. It was very important to distinguish essential foodstuffs from true stimuli to growth. In the case of repair of wounds it had hitherto been customary to ascribe growth to the removal of the restraining effect of the adjacent cells. The proliferation occurred when the tissue balance was disturbed and continued until it was restored. The question was whether the phenomena could be explained on the hypothesis of definite stimuli supplied by leucocytes or other cells. Tissue cultures were unsuitable for determining the matter as in them the normal cell relationships were wanting and the fact that embryonic juice promoted proliferation was not enough to show that it was effective by itself. An example was still needed to show that such stimuli could cause proliferation when the relationship of cells was not disturbed. It must be borne in mind also that repair in mammals was the representative of the more complicated process of regeneration in lower vertebrates which latter in its turn was a reproduction of the phenomena of ontogeny. At present it did not appear justifiable or possible to explain the proliferative processes in repair as being the result of growth promoting substances alone.

With regard to neoplastic proliferation, it was important to recognize as regards conditions of occurrence two types of tumour—namely, that which might result from irritation of previously normal tissues and that which followed some disturbance of development. The question as to what extent tumours arose from displaced cells or 'rests' was a separate matter but the all important fact was that there were various kinds of tumour—such as neuroblastomas and blastocytomas—which must arise from cells which had not reached the adult state and which were sometimes multipotent. The recent work on tumours of the central nervous system illustrated this in a striking way, as it appeared that a growth might originate at any stage in the differentiation of the original medulloblasts. Again, a simple hepatoma resulting from congenital abnormality might become malignant and give rise to metastases, in cirrhosis of the liver the compensatory hyperplasia of the liver cells might pass on to neoplastic proliferation, and,

again, malignant properties might appear. What might be called the life history in the two instances was widely different, while the end-result was the same. Any explanation of tumour growth brought forward must apply to the two types.

Professor J SHAW DUNN (Manchester) thought that in spite of greatly varying cellular structure there was much in common in the general biological aspect and behaviour of simple tumours, while the malignant forms, though derived on the one hand from connective tissue cells, on the other from epithelial, and differing in intimate architecture on that account, showed more features of similarity than of difference, and were clearly separable from other active proliferative processes of known causation. The whole group of tumours retained a certain uniformity of general idea, which was borne out by the not uncommon occurrence of linking forms and of simple growths which ultimately became malignant. It appeared reasonable to suppose that, if new growths had not a common cause, yet there must be in the genesis some general etiological principle which would link together this group of morbid activities, somewhat as the conception of organismal infection linked together the diverse group of bacterial diseases, but a review of the etiological factors known to be concerned in neoplasia showed little or no suggestion of any such unifying consideration. Recent experimental work with certain chemical substances had shown that tumour growth, often with malignant characters, could be induced after sufficiently prolonged application, and this not only provided a direct explanation of a limited number of human growths, the industrial cancers, but suggested a similar explanation of some tumours of the alimentary tract where the irritating agents were not definitely isolated. Pre-existing damage was another factor that in some way led to cancer formation. Cancer of the liver was very rare apart from hepatic cirrhosis, and it developed on the latter in at least 3 per cent of cases. Cancer of the kidney was associated with pre-existing renal lesions. All were familiar with the development of epithelioma on scars. Again, the development of malignant tumours from simple tumours was not uncommon, and it was hardly possible to escape the conclusion that the more serious condition was predetermined in the earlier cellular activity, however that, in its turn, might have been caused. The influence of true hereditary factors in the production of tumours was evident from the occurrence of such malignant forms as retinoblastoma, more simple tumours as angioma and neurofibroma, and simple tumours liable to become malignant, such as polyposis coli. In neurodermatitis pigmentosa the coincidence of two factors would appear to be necessary—an hereditary susceptibility, and the irritant action of the physical agency, sunlight. Whatever were the factors so diversely concerned the end-result was the same in all cases, and it was hardly legitimate to ignore the implications if an attempt was being made to discover any general etiological principle. The question as to whether this principle might be of the nature of a special type of organism had not been raised there, as there was no evidence available in relation to human or even mammalian growths which pointed definitely in that direction. The production of some tumours by external chemical agencies, and the predominant part played by true hereditary factors in the genesis of others, were facts which did not encourage belief in a specific organismal cause. The available data rather suggested that enlightenment must await a more complete knowledge of the conditions regulating cellular proliferation and the harmonious relationship between different kinds of cells in the tissues.

Professor E H KETTLER (Cardiff) believed that it was generally assumed that malignant and innocent tumours and simple hyperplasias were merely exaggerations of the normal physiological process of growth, but he thought that it might be doubted if these phenomena were really comparable, or even that all forms of malignant growths were examples of the same process. Was it justifiable to regard growth or enlargement as necessarily the same thing as cell multiplication? What was the difference, if any, between local and general growth? Even if these forms

of protoplasmic activity were fundamentally similar, must be admitted that they might be due to several different causes. The power to grow might be latent in it was inherent in all living matter, and might reveal itself at any time in response to an appropriate stimulus. It would scarcely seem necessary to seek for any further explanation of the ordered enlargement or growth of the developing individual than this inherent property of the cells, but even this form of growth was subject to control. It might, for example, be inhibited or increased by the presence or absence of various hormones. The phenomenon, therefore, was not simply an example of the inevitable performance of an inherited function, whether spontaneous or in response to stimulation, in adult life this became even more apparent. A substance which stimulated cells to multiply was produced in the degeneration of cell protoplasm, and presumably the cellular proliferation by which the healing of wounds was brought about was due to its presence. Its action could be demonstrated *in vitro* by the technique of tissue culture, and its presence had also been shown in the intact malignant cell. The suggestion was that the malignant cell differed from the normal in that there existed within it the growth promoting substance which normally was found only when cell protoplasm broke down. If this view was correct it was obvious that malignancy was not merely an exaggeration of the normal physiological process of growth, for the malignant cell had definitely acquired a new property. It was scarcely likely that the matter was so simple as this. The development of a malignant new growth appeared to be accompanied by a constitutional change, according to Murray's experiments, so that the other tissues of the body no longer reacted in the normal way to carcinogenic agents. Even in the simple healing of wounds the presence of some other controlling force besides the growth stimulating substance seemed probable, for how otherwise could be explained the nice adjustment of the covering epithelium in the healing of superficial wounds?

Though it was necessary to guard against too wide an application of the results of tissue culture, some observations by the late Dr Strauchen seemed highly significant, he had pointed out that the cell was at its most plastic and impressionable state during division, and had suggested that cell division was the process by which the cell could best reorganize its protoplasm so as to adapt itself to altered physiological conditions. If the cell was in a state of physiological equilibrium it remained quiescent or vegetative, but should this equilibrium be upset, usually by alterations in environment, it adapted itself by such a mingling and reorganization of its protoplasmic molecules as could only occur in the process of division. From this point of view, therefore, the growth or enlargement of a tissue might be the accidental result of a cellular proliferation which itself was purely protective.

Professor M J STEWART (Leeds) stated that a careful scrutiny of necropsies during many years for the presence of adrenal rests and epithelial heteroplasias of the stomach had shown that such occurrences were by no means uncommon, that they were unduly predisposed to tumour formation, in comparison with other tissues, could not be conceded. It was a different matter, however, to maintain that Cohnheim's theory thereby failed. It had to be admitted that no direct proof of Cohnheim's hypothesis had as yet been forthcoming, in the nature of things it was doubtful if this would ever be attainable. Yet the hypothesis remained an attractive one, especially to explain the origin of teratomas in situations other than the sex glands. It was not suggested that the hypothesis was wholly sufficient, but it might well cover a part of the truth. In addition some factor or factors must be present to account for the onset of proliferation. Most of the some additional explanation necessary in regard to malignancy—such, for example, as Adams' "theory of growth theory." It had been maintained that the fast growing cells of fully differentiated tissues were not capable of proliferation, and that all forms of tumour growth were by accident or from error and tear, as made good by multiplication of physiologically hypoplastic cells constituting the germinal and regenerative cells.

tissues. That was merely a generalization from what must obviously occur in the maintenance, for example, of surface squamous epithelium where proliferation was confined to the differentiated germinal layer. It did not seem a great step from such a conception to Cohnheim's theory of cell nests in relation to cancer. That cancer cells were able to remain in the tissues for considerable periods without appreciable proliferation was clearly shown by the experiments quoted by the opener of the discussion and by the numerous instances on record of metastases remaining dormant and inactive over many years.

Professor J. LOFFAN SMITH (Edinburgh) said that while recent investigation of tumour growth had dealt chiefly with etiology, the progress made had revived the question of the nature of the process. The discussion of this aspect of the subject had long been familiar in the contrast drawn between tumour, hypertrophy, repair, and regeneration. More recently cytologists had taken up the study of cell differentiation especially in relation to changes in ectoplasm. The application of biological methods to corresponding changes in tumour cells was a problem for future investigation. A certain approach to it had been made in Unna's study of skin cancer. Adopting as a basis of classification the architecture of the normal skin, he opened up a field of investigation. In the lower layers of the rete mucosum the cells maintained active division and afforded an example of continued growth. On division of the cells in these basal layers the growth of the skin depended. Two types of cell were produced—one which remained a basal cell with power of continuous division, and another which passed from the basal layer to become a prickle cell finally receiving the form and composition of a surface squamous cell. With this differentiation the power of division was gradually lost. There was therefore a double product from the original division. The architecture of the skin resulted from the production and maintenance of the two types of cell. In the one type there was continued division originating new basal cells and in the other there was differentiation in the direction of keratin scale formation and the power of division was lost. The haemogenetic tissue afforded another clear example of biological architecture. The primitive blood cell in division, continuously maintained, produced cells which remained primitive blood cells and at the same time cells to become gradually transformed into red corpuscles, the e, like the squamous cells had lost their power of division. In cancers of the skin, as Unna had shown the normal architecture was disturbed in a considerable variety of way. With this principle of interpretation as a guide he reached a classification of cancer of the skin according to the type of disturbance. Whatever might have been the result of recent work on etiology it must be acknowledged that it had provided a new means of investigating experimentally the process of cancer growth in relation to the process which in the normal tissue resulted in its biological architecture.

## LACRYMAL OBSTRUCTION ITS NASAL ORIGIN AND INTRANASAL TREATMENT \*

BY

F. HOLT DIGGLE OBE, FRCS

Honorary Surgeon to the Ear and Throat Department, Ancoats Ho-pital, Manchester and to the Manchester Ear Ho-pital

The exact pathology of lacrymal obstruction is still somewhat obscure. The part played by diseases or abnormalities of the nasal passages and accessory sinuses is considered to be more important than descending infections from the conjunctival sac. According to Kuhnt, nasal diseases are responsible for 95.7 per cent of cases of lacrymal obstruction while a leading textbook on ophthalmology quotes as causes inflammatory conditions of the nasal mucous membrane, simple catarrhal tuberculosis and syphilis, ulcers of the nose, tuberculous, syphilitic and lupoid and nasal tumours, especially polypus blocking the lower orifice of the nasal duct. Bruckner, although he regards nasal causes

as uncommon admits that in the majority of cases diseases of the lacrymal apparatus are nasal in origin.

The purport of this paper is to report the results of an investigation into the nasal condition of 120 cases of lacrymal obstruction observed by me during the last four years through the kindness of my colleagues at the Manchester Eye Hospital.

### Incidence

The susceptibility of the female sex to lacrymal obstruction is a well known fact, and, I believe, never been satisfactorily explained. In the present series 102 cases occurred in females and 18 in males.

The following table giving the age incidence of the disease shows that the greatest number of cases occurred between the ages of 30 and 60, but that of the three decades in this period the numbers of cases were practically equal.

1-10 years	4 cases
10-20	5
20-30	12
30-40	26
40-50	34
50-60	25
60-70	9
over 70	3

The oldest was 74 and the youngest 6 years. The shortest duration of symptoms, such as epiphora, was six months, the majority, however, had presented symptoms for two years or more.

### Etiology

Injury.—Any injury in the region of the inner canthus producing either a fracture of the infra-orbital margin or of the frontal process of the superior maxilla may mechanically obstruct lacrymal drainage. Similarly a chronic traumatic periostitis in the region of the lacrymal fossa following injury without fracture might be an etiological factor. A definite history of injury was obtained in only 5 cases (4.1 per cent). 2 developed an abscess over the eye immediately following the injury with subsequent epiphora, whilst 3 presented a definite scar, and in all the epiphora began immediately upon receipt of the injury.

Breadth and Width of Nose and Nasal Passages.—Whitnall has shown that the breadth of the lacrymal fossa varies with the shape of the skull, being wider in the brachycephalic and narrower in the dolichocephalic types. The lacrymal fossa is deepest at its base where it joins the naso-lacrymal canal, but Gerard has found that the canal is narrowest at the orbital opening, its lower end under the inferior turbinate body being wide and almost funnel shaped. Moreover the direction and inclination of the lacrymal passage is dependent upon the configuration of the facial skeleton, being influenced by the breadth of the bridge of the nose and of the nasal aperture, as also by the development of the maxillary sinuses. Testut showed that, seen in profile, the lacrymal fossa and canal slope gently backwards, forming an angle of 15 to 20 degrees with the frontal plane, while, viewed from in front, the fossa slopes outwards towards its lower end and the canal slopes inwards towards its nasal opening, together forming a curve the concavity of which is directed inwards, the summit being near the upper orifice of the canal—that is, the orbital opening. This lateral obliquity of the medial wall of the fossa is more marked in narrower noses. A narrow lacrymal fossa or an acutely curved lacrymal passage may more readily predispose to obstructive symptoms. The breadth of the nose and the width of the nasal passages were found to be distinctly narrow in only 13 cases (10.8 per cent), and in only one of these was the epiphora bilateral. The intranasal prominence of the lacrymal groove was a distinct feature in all these cases. In 15 cases (12.5 per cent) the nose and nasal passages were noted to be unusually wide and the epiphora was bilateral in 6 cases. In none of the series was the size of the nasal passages dependent upon any deviation of the nasal septum.

### Nasal Pressure Deformities and Reflex Neuroses

Onodi considers that "the ostium of the nasal duct may be wholly or partially occluded by hypertrophy of the turbinates, by polypoid and papillary degeneration of the anterior end of the inferior turbinate, by foreign bodies, dental cysts, syphilitic and tuberculous lesions, etc." And

\* Read in the Section of Ophthalmology at the Annual Meeting of the British Medical Association, Edinburgh, July 1917.

again, "Changes which take up space or exercise pressure, such as tumours, polypi, the so-called bone cysts, cystic swelling of the middle turbinate, mucous or purulent, spurs and deviations of the nasal septum, will have a like effect." Apart from actual obstruction in the lacrimal passages, Onodi further considers that "there may be a reflex neurosis set up which can evoke from the nose a reflex epiphora." Fischer, quoted by Onodi, describes the cure of a large lacrimal sac the size of a hen's egg following the resection of the anterior end of the inferior turbinate body.

It is difficult to realize how pressure from an enlarged turbinate bone, deviated septum, etc., can mechanically obstruct a membranous lachrymo-nasal tube, lodged as it is in a bony canal. Alterations in the width of the nasal passages following such lesions, which would link the lacrimal canal, are a rarity. Stimulation of the nasal branches of the trigeminal nerve from nasal pressure deformities may reflexly excite excessive lacrimal secretion with resultant epiphora, but, without some obvious intranasal lesion which would mechanically obstruct the lacrimal passage, permanent distension of the lacrimal sac does not seem to me to be possible.

**Enlarged and Displaced Middle Turbinates.**—The middle turbinate was noted to be moderately enlarged in 12 cases (10 per cent), occupying the space between the nasal septum and the outer nasal wall, but with no deflection of the nasal septum. In no instance was there massive cystic enlargement of the turbinate. Six of the series presented a distinctly oedematous appearance of the anterior end of the turbinate body. In two cases (not included in the above) the turbinate enlargement was on the side with no epiphora. The anatomical relation of the middle turbinate body to the lacrimal fossa is of interest, since Thoisch found that in a series of 79 specimens the middle turbinate in 52 instances lay completely behind the lacrimal groove. In four instances (33 per cent) the middle turbinate was displaced outwards without any enlargement and not due to a deviated nasal septum. The peculiarity of these displaced turbinates is that the anterior tip of the lower border was distinctly curved outwards and pressing against the outer wall.

**Deviated Nasal Septa.**—In only 10 cases (8.3 per cent) was the deflection of the nasal septum severe enough to displace the middle turbinate against the outer wall. The epiphora was in nine instances on the side of the septal deflection, while the tenth presented a bilateral epiphora which was worse on the side of the deflection. In 15 cases the septal deviation was too slight to have any bearing on the etiology, while in 7 cases the septum was deflected towards the side with no epiphora.

**Inferior Turbinate Bone.**—Considering the anatomical relationship of the inferior turbinate body to the nasal opening of the lacrimal duct it might be thought that lesions of the inferior turbinate would be frequently seen in cases of epiphora. There were, however, only two instances (1.6 per cent) of moderate enlargement in the present series. It is, I believe, now generally accepted that the site of obstruction in the majority of cases is at the neck of the sac and not at the nasal orifice.

**Rhinitis.**—Atrophic rhinitis, usually a bilateral disease, was present in 7 patients (5.8 per cent). The epiphora was bilateral in 4 and unilateral in 3 instances. Hypertrophic rhinitis occurred in 6 cases (5 per cent), with bilateral epiphora in 3 patients, all boys, aged 9, 10, and 13 years, with marked hypertrophic rhinitis. Simple catarrhal rhinitis was only seen twice (1.6 per cent).

#### Accessory Nasal Sinus Disease and Lacrymal Obstruction

The lacrimal fossa in its upper half is related to the anterior ethmoidal cells, its lower half being related to the middle nasal meatus. According to Whitnall, in the majority of instances (54 per cent) the anterior ethmoidal cells extend as far forwards as the anterior margin of the lacrimal groove and even into the frontal process of the superior maxilla. Less frequently the lachrymo-maxillary suture (32 per cent) or the posterior margin of the lacrimal fossa (14 per cent) forms the anterior boundary of the ethmoidal labyrinth. Pus arising from a suppurative ethmoiditis not infrequently spreads through the

lacrimal bone into the lacrimal groove and point out the inflammatory condition of the anterior ethmoidal cells similarly extend through the lacrimal bone producing a local periostitis in the lacrimal groove. The neck of the lacrimal sac may thus be constricted. Moreover the anastomosis existing between the venous and lymphatic plexuses of the ethmoidal, as also the maxillary, sinuses and the mucous lining of the lacrimal drainage apparatus would appear to render the latter susceptible to obstructions in inflammatory states of these sinuses. The above occurred eight times (6.6 per cent) in the present series. There were two cases of closed empyema, four cases of cystic degeneration, and two or non-suppurative ethmoiditis with single polyp. There was no case of extensive suppurative ethmoiditis with multiple nasal polyp, nor was lacrimal obstruction found associated with an empyema of the maxillary sinus.

**History of Nasal Disease.**—A history of previous nasal trouble was a rarity, either spontaneously stated by the patient or admitted after interrogation. The majority of patients could give no explanation for the onset of the lacrimal obstruction and denied any knowledge of previous nasal trouble.

Table showing Incidence of Nasal Diseases of No. of cases examined 120

Nasal Lesion	Per cent Incid.
Injury	4.1
Breadth of nose and nasal passage—	
Narrow	10.8
Wide	13.3
Enlarged middle turbinate bones (moderate only)	10.0
Misplaced middle turbinate	3.3
Deviated nasal septum	8.3
Enlarged inferior turbinates	1.6
Rhinitis—	
Atrophic	5.8
Hypertrophic	5.0
Simple	1.6
Ethmoiditis—	
Closed empyema	1.6
Cystic	3.3
Non-suppurative with single polyp	1.6

#### Results of Intranasal Treatment

To test further the etiological factor of such nasal abnormalities as were discovered, treatment for them which was undertaken with the following results:

No relief of the epiphora or lacrimal sac distension followed non-operative treatment for the various types of rhinitis, except that in two cases of marked hypertrophic rhinitis some amelioration of the epiphora resulted from shrinkage of the inferior turbinate body induced by the electric cautery. In both of these cases the epiphora was very pronounced and the improvement would seem to follow the relief of the nasal pressure reflex.

The nasal septum was straightened, and where necessary the anterior end of the middle turbinate bone resected, in ten cases, but with no alteration in the epiphora.

No cure of the lacrimal obstruction followed ablation of a cystic ethmoidal labyrinth (four cases).

Complete recovery of the lacrimal obstruction followed drainage of pus in the two cases of closed ethmoidal empyema. The special interest of these two cases is the fact that there was no history of nasal purulent discharge, no free pus in the nose, and, in the first case encountered, the existence of pus was not suspected until operation. In each case the ethmoidal labyrinth had been converted into one large single pus sac.

#### Intranasal Drainage of the Lacrimal Sac (Whitnall's Operation)

This method of treatment, now so familiar, is the establishment of intranasal drainage of the lacrimal sac by removal of its inner nasal wall after exposure through the nose.

Intranasal drainage was performed 45 times, with complete recovery in 32 (71.1 per cent), moderate improvement in 8 (17.7 per cent), and failure in 5 (11.1 per cent). The term "moderate" is reserved for those cases in which slight epiphora when out of doors but in closed room the sac no longer exists. Included in this category are those who, when examined, present

tears at the inner canthus though the patients are quite satisfied. No case is included in the above figures in which operation has been performed less than six months.

J. S. Fraser, who has had a large experience of this operation, gives 73.4 per cent cures, and thus I think, is the experience of all those who have assayed the procedure on my large scale. The operation should not be attempted in the presence of acute dacryocystitis. Internal incision and drainage must first be established and the inflammatory condition allowed to settle down. A slit canaliculus does not preclude a perfect result.

#### Conclusion

It would appear from the present investigation that the incidence of nasal abnormalities, deformities, and diseases, in cases of established lacrimal obstruction, is a rarity. The failure in relieving the lacrimal obstruction following the resection of such nasal lesions was found with the exception of suppurative rhinitis which is in itself rare seems to preclude them as etiological factors in lacrimal obstruction. The absence of a history of nasal trouble in the majority of cases as also the rarity of the incidence of nasal disease would seem to render the nasal origin of lacrimal obstruction "non proven." That there is a nasal cause would seem to be undoubted but its exact pathology and incidence still needs further investigation.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL

#### INTRATRACHEAL INJECTION OF LIPIODOL GENERALIZED IODIDAL RUPTION DLATH

Lipiodol consists of iodine dissolved in poppy oil and gives a very dense shadow under X-rays. It is considered a safe medium for injecting into the spinal canal for intratracheal injection and for injection into the uterine cavity and lipiodol tubes. Its use has now become so widespread that its untoward effects have a general interest.

L. W., a commercial traveller aged 40 had two attacks of pneumonia the first in February 1926. A nervous breakdown with loss of memory followed the removal of many teeth immediately after this first attack. In October 1926 he was in a nursing home at Margate for chest trouble for three months. He was admitted to the London Hospital on March 6th 1927 for a pulmonary and pleural eruption which had lasted since injections of antipneumococcal vaccine in 1926. The palms and sole had peeled twice since and he had been taking an arsenical medicine regularly.

He was a greynosed worried-looking man with a short frequent cough and greenish morning expectoration. The pulse was 83 to 96 and regular there was no fever the urine was natural the systolic blood pressure was 146 mm. of mercury the chest was symmetrical and resonant to percussion with a coarse bronchial rale on the left side. Heart abdomen and central nervous system presented nothing abnormal. There were numerous scattered purulent follicle in the lower abdomen and small scattered pustules in the hair of the lower abdomen and pubic region. The skin of the whole body was dry and slightly rough. The nails were curved over a little at their tip.

On March 11th a physician reported. Physical signs are suggestive of an old arrested fibrous lesion of slight extent at both apex but more in the left than in the right. This seems to be borne out by radiological examination. Investigation by X-rays after lipiodol injection would be useful.

The patient was seen by an aural specialist on March 14th on account of vertigo. No aural cause was seen there was light on in Germany. The stapes and tubular had been operated on.

On March 31st an injection of 20 ccm. of lipiodol was given by the intratracheal route and a X-ray plate of the lung taken. Laboratory examination showed that the blood cholesterol was 109.4 mg. per cent. The Wassermann reaction was negative and tubercle bacilli absent from the sputum (three investigations). Pans from an abscess of the abdominal wall yielded *Staphylococcus*.

aurus Blood culture (May 7th) was negative. Cultures of vesicles on forearms (May 3rd) were all sterile.

The temperature had been very irregular and had risen to 101.0 by April 9th. On April 19th great numbers of small boils were appearing over the trunk and limbs. The voice was very hoarse and the cough more frequent and ever. On May 6th both forearms were covered with vesicles. Three days later the general condition was definitely worse. He was very weak clear mentally, complaining of no pain unable to cough with any force. He showed umbilicated driving vesicles all over the trunk face and limbs. On the legs many small scabs had come away leaving raw granulating areas. Several who saw the patient during the last three days were suspicious of variola. No contact case of variola developed. The vesicular fluid did not give any colour with starch paper. No iodides were found in the urine.

The patient died from bronchitis and heart failure on the evening of May 10th. No post mortem examination was permitted. During his stay in hospital the patient had been treated by opiate doses of X-ray barbitone for sleeplessness varied by chloroform and local dressing.

This patient began to go downhill very definitely after the intratracheal injection of lipiodol. The eruption was one of the recognized types of rash that may follow the absorption of iodides.

W. J. O'DONOVAN, O.B.I., M.D.,  
Physician in charge of Skin Department, London Hospital.

#### PALPABLE GALL STONES IN AN UNDISTENDED GALL BLADDER

The following case is of interest inasmuch as I have never before seen a case or heard one demonstrated where gall stones in an undistended gall bladder were palpable through the abdominal wall.

A man aged 46 consulted me in May 1927 for an attack of pain in the upper abdomen. It was not extreme nor definitely of a colicky type but was described more as a soreness.

The patient gave a history of repeated attacks of similar pain at intervals during the previous five years. The first, in 1922 was accompanied by a rigor and by vomiting but on subsequent occasions there had been no vomiting. The only physical sign present was tenderness on pressure in the epigastrium and in the right and left three-fourths nothing in the nature of a lump could be felt on his first visit.

On July 14th he again presented himself as he had another attack of pain. On examination a hard spherical lump which seemed the size of a large marble was felt some two inches below the tip of the ninth right costal cartilage. It could be pushed about freely within the radius of about two and a half inches and pressure on it caused definite uneasiness.

In spite of the fact that the history was somewhat suggestive of cholelithiasis or at any rate cholecystitis I felt that the lump by virtue of its ease of palpation on hardness and mobility could hardly be the gall bladder.

A barium meal having revealed no abnormality of the stomach or duodenum laparotomy was advised to ascertain and deal with the cause of the repeated attacks of pain. The patient was admitted to Swansea General Hospital where he was kept under observation for a week. On admission the presence of the lump was confirmed by Mr. C. L. Isaac and his house-surgeon Mr. A. H. Holme. Three days later it could not be found but two days subsequently it was again felt in its original position and of its original size hardness and mobility.

Laparotomy was performed on July 25th by Mr. C. L. Isaac who on opening the abdomen immediately found and demonstrated the gall bladder undistended but obviously inflamed freely movable and full of stones. Cholecystectomy was performed and the patient made a good convalescence.

Although of lean build, the patient was not wasted and his abdominal muscles were quite well developed.

SWANSEA G. H. KINGSTON KNIGHT

#### HEREDITARY DEFORMITY OF THE FINGERS

The recently reported case of this condition prompts me to record one somewhat similar with which I came in contact a few weeks ago. In my case the feature on which I wish to lay stress is the fact that the deformity has been transmitted through both male and female members of the family at also differs anatomically from that already published.

A girl aged 6 years said by the mother to be a 6½ months child exhibited the following deformity. Each finger consisted of only two phalanges the proximal ones being of average length but the distal shorter than the normal. The latter had rudimentary nail which did not extend to the ends of the fingers. The thumbs had each only one phalanx bearing a shortened nail similar to the fingers. The child's feet showed no abnormality though her sister aged 10 had slight webbing of the toes. One of her brothers aged 14 had no nails on the second and third digits in adult brother with this deformity suffered little or no disability in earning his livelihood as a labourer.

<sup>1</sup>Valentine C. Diagnostic use of Lipiodol, *London Hospital Gazette* 1927, vol. 2, p. 2.

anaemia was present in all forms of heart failure, but the irritability of this type of breathing in congestive failure was probably associated with the necessity for free pulmonary ventilation in the production of the alternating phases of apnoea and hyperpnoea. The peculiar features of paroxysmal dyspnoea or cardiac asthma were described, and especial attention was directed to the beneficial action of morphine in ending the attacks. A study of these paroxysms suggested that in certain circumstances dyspnoea might be a dangerous reaction which might drive a damaged heart to final failure, and that morphine should be used more freely than was customary in the treatment of dyspnoea. The danger in the use of morphine was that it depressed the respiratory centre so that an increase in the anaemia might result from inefficient oxygenation of the blood in the lungs. When the centre was fatigued this danger would outweigh the benefits, but if the methods for administering oxygen were improved the use of morphine in the relief of dyspnoea could be greatly extended.

#### Extensive Oedema of the Foot

Mr GIRDLESTONE showed a girl, aged 18, who had been sent to him by Dr Frankland West in 1923 with the whole leg and foot intensely swollen and oedematous, and severe pes cavus. There had previously been ulceration of the foot which was suggestive of perforating ulcer. The condition had been coming on gradually for a long time. It was later elicited that the girl had cut the sole of her foot some years before. She had never been abroad, no filaria were found in her blood, and there was no history of streptococcal lymphangitis nor of any streptococcal infection. At that stage no warmth of the foot was noticed. The oedema yielded slowly to elevation, the claw-foot remaining. She was admitted to the Wingfield Hospital last March and an operation was performed including tenotomy of the short muscles of the foot, wrenching with Thomas's wrench, amputation of small toe of the left foot, filleting of the fourth toe, transplantation of the extensor proprius hallucis to the neck of the first metatarsal, and arthrodesis of the interphalangeal joint of big toe. No abnormalities of the tissues were discovered. The foot healed well, but soon after removal of plaster and the resumption of walking in an ordinary shoe a perforating ulcer appeared under the third metatarsal head. This had persisted to the present, there being a slight sero-purulent discharge from it, but no granules. The foot was now felt to be hotter than the other, and there was considerable oedema of the foot and leg again. The x-ray picture showed extreme rarefaction of the fourth and fifth metatarsals with pathological fracture of the neck of the fourth and some fungating bone round the fourth and fifth metatarsal heads. All this time the patient walked perfectly and without any pain whatever. This latter point in particular together with the x-ray picture, indicated the possibility of a trophic condition associated with some lesion of the central nervous system. Recently Dr A. G. Gibson had found no sign of such lesion, he had, however, suspected the possibility of mycetoma (Madura foot). He had taken a culture from the depth of the sinus and grown a mould.

Dr A. WATERFIELD stated that he had seen a large number of Madura feet in the Sudan, but none resembling this. There had never been such extensive oedema and the lesion had been much more localized.

#### Pathological Specimens

Dr GIBSON showed (1) A small carcinoma occluding the lumen of the common bile duct near the entry of the cystic duct which had caused an enlargement of the gall bladder and extreme jaundice. In the hepatic ducts there was a general cholangitis with abscess formation throughout the right lobe of the liver. The patient had died from cholangitis and suppression of urine. (2) A heart from a man aged 63 which showed a healed patch of ischemic necrosis with marked absorption of the inner part of the wall of the left ventricle in the field of the descending branch of the left coronary artery which, though patent at its origin and for 1½ inches from its origin, became extremely narrow and admitted only a pin. The main

branch of the left coronary artery was blocked by a recent clot. The patient had had four years previously a cardiac attack, with breathlessness, pain, and cyanosis from which he had completely recovered, except for slight attacks of thoracic discomfort. He had had a similar attack a few days before death.

## Reports of Societies.

### PAINLESS CHILDBIRTH

At a meeting of the North of England Obstetrical and Gynaecological Society in Liverpool on October 28th, the President Professor W. GILBERT SHAW, in the chair, Mr S. GEORGE WILSON (Liverpool) read a paper on "twilight sleep."

Mr Wilson said that he had investigated the question of scopolamine narcosis on the lines recommended by the committee appointed by the Section of Obstetrics and Gynaecology of the Royal Society of Medicine in 1917. He had treated a series of 32 cases which included 16 primiparae and 16 multiparae. He considered his results under the various heads adopted by the committee. To exclude sensory impulses a quiet room was selected which could be darkened. Cotton wool soaked in oil was placed in the patient's ears, she was kept in bed and discouraged from talking, conversation being carried on in whispers. Observations were made, and the delivery performed, by the light of a small shaded lamp. The injections were commenced in primiparae when the cervix was dilated to the size of two fingers, and in multiparae when labour had definitely commenced. The first injection consisted of omnopon grain 2/3 (Rocho) and scopolamine hydrobromide grain 1/150 (B and W). Each subsequent injection consisted of scopolamine grain 1/450, and in no case was the omnopon repeated. The second and third injections were given at hourly intervals. Subsequent injections were given at longer intervals—from one and a half to two hours, according to the condition of the patient. If labour ceased entirely as it did in four cases, the injections were withheld until it recommenced. The average number of injections was 4.5. Injection of pituitary extract was employed in 17 cases (9 primiparae and 8 multiparae) chiefly in the second stage to augment the expulsive contractions of the uterus. The amount of pituitary for a single injection never exceeded 0.25 ccm. In primiparae the average duration of labour was fourteen hours forty-five minutes, and the proportion after commencement of treatment was five hours forty-one minutes. In multiparae the average duration of labour was sixteen hours twenty-six minutes, and the lapse of time after commencement of treatment was six hours five minutes. The longer period in multiparae was explained by the exceptional length of some of the labours. In all but two cases the uterine action was altered by the injections, lengthening of the intervals between the contractions being the chief alteration. The strength and duration of individual contractions were also diminished. These changes were most marked between the second and third injections during the second hour, and were ascribed to the action of the omnopon for in the majority of cases the pains increased again in force and frequency to culminate in expulsion of the foetus. In four cases labour ceased altogether during the treatment, in one case for eighteen hours, another for six, and in two others respectively for four and two hours. Voluntary expulsive efforts did not arise automatically, but as a rule the patient made them when instructed to do so. The pulse and respirations were unaltered. Observations on the blood pressure during labour did not show any relation between the height of the blood pressure in millimetres of mercury and the character and frequency of the uterine contractions. It was noted that, as a rule, the blood pressure tended to fall during labour. Thirst was noticed invariably and nausea occurred in a few cases, some of the patients complained bitterly of the pain especially in the second stage. Sleep between the pains was present in every case,

slight restlessness and a moderate amount of mental confusion were noted as being associated with the uterine contractions in the most successful cases. Marked restlessness, difficult to control, and tending to occur in periods of uterine relaxation, was taken as an indication for postponing the next dose of scopolumine. Uncontrollable excitement was never seen. The pupils were normal and reacted to light. The corneal reflex was also normal. A key or a pair of scissors was usually the object shown to the patient for the memory test. The memory of the object shown was never at fault. General anaesthesia was only induced in five cases at the end of the second stage, in three cases for forceps extraction, and in two cases in which it was feared anaesthesia had been lost owing to the interval over which injections had been stopped when labour had ceased. Delivery of the child was spontaneous in all but four cases, when forceps were used, two of these patients were multiparae with contracted pelvic outlets, and two primiparae, one with twins, and the other with poor pains and a rigid perineum. In the latter case analgesia was so good that in anaesthesia was unnecessary. In one case the placenta was delivered by Credo's manoeuvre. In nine cases it was noted that haemorrhage associated with the third stage was more than usual, but it was never excessive. In one case the child was stillborn, this occurred in a primipara with premature rupture of the membranes and weak pains. In the other cases the children were born alive and were discharged healthy. In no case the child showed varying degree of apnoea, but could come on later on being left alone in a warm place. All the babies were thirsty for the first twenty-four hours. Sleep after delivery was untroubled and it was found that the better the sleep the more successful was the case. The establishment of anaesthesia only was attempted, as the condition of mind in a child too great an intoxication. "Flash" of memory was produced by stimuli being applied during the coming of the anaesthesia. The anaesthesia was usually, however, applied. The best guide to the condition of the patient between the pains, and her reaction to uterine contractions. The optimum condition was that of amnesia between the pains, with a moderate degree of sedation and muttering delirium associated with the uterine contractions. The cases fell into three groups: (1) complete amnesia in which the patient remembered nothing of the labour (17 cases), (2) incomplete amnesia in which the patient had islands of memory formed and remembered incidents during the labour (17 cases), (3) failed amnesia in (3 cases). During the puerperium the condition of the patient was markedly better than in normal case, and there was less exhaustion. Three cases of pyrexia occurred in association respectively, with pyrexia, suppurative inflammation of the perineum and retention of membranes with delayed involution of the uterus. Lactation was normal in all cases. Mr Wilson concluded that the treatment was very good for the mother, lessening the mental and physical strain of labour, but it exacted unremitting attention from both the medical practitioner and the nurse. The uterine action was definitely diminished, and so labour tended to be prolonged. This might be counteracted, however, by the use of pressor substances, or by methods of artificial delivery. There was no danger, either to mother or child, if the effects of the injections were carefully observed. The memory test was a disadvantage. Strict precautions must be taken to exclude all adventitious stimuli.

The President said that twilight sleep had been much boomed when introduced twenty years ago. It then fell into disrepute and the time had now come to take a clear and dispassionate view of it. He himself did not make use of it to any great extent. The great disadvantage was the amount of time involved.

Dr Lacey asked if Mr Wilson had noticed an abnormal number of persistent occipito-posterior positions of the vertex. He thought that the opinion was due to delivery rather soon after the injection of morphine. He used ether at the end of the second stage to diminish the pain, and it also tended to stimulate the infant. He agreed that the use of pituitrin was necessary to excite the uterine contractions. He gave scopolumine grain 1/100 for the

first dose, and grain 1/200 subsequently. A good nurse was essential and attention to the bladder was necessary.

Professor MISS PHILLIPS asked if the patients complained of drowsiness of the mouth. He said also that the preparation of scopolumine used was of importance.

Mr WILSON, in reply, said that he had not had any persistent occipito-posterior positions in this series. He did not consider it was true "twilight sleep" if an anaesthetic was used. He had not had any patients who remembered then thrust during the labour.

#### Sequel of Radium Application

Mr W. W. KING (Sheffield) showed a specimen of carcinoma of the cervix arising in a case in which radium had been inserted for the treatment of menopausal bleeding.

The patient was a 2 para, aged 50. Four years before he had treated her with radium sulphate in the uterine cavity for menorrhagia due to a fibroid the size of a golf ball. The cervix was noted as healthy at the time. Five months ago a blood stained discharge had commenced, which recently increased in quantity. A fairly advanced carcinoma of the cervix was found, and the uterus was removed by Wertheim's hysterectomy. The specimen showed that the cervix was occupied by an extensive growth, apparently a squamous-celled carcinoma, spreading on the surface of the cervical mucosa. The cavity of the uterus was practically obliterated. The fibroid present at the fundus was compact and cellular. The ovaries showed no ova in the cortex but marked hyaline changes in the vesicular walls.

Mr J. L. STACY asked if any cervicitis had been noted as a result of the action of the radium before the onset of the carcinoma, and Mr KING replied that there had been no symptoms of it.

Dr LEITH MURRAY (Liverpool) showed sections of the endometrium and ovary after intracavitary radium.

The uterus and ovaries were removed from a nullipara aged 39, who had had a full sterilizing dose of radium inserted into the uterus four months previously to induce the menopause for pain and menorrhagia. Persistence of the pain, due to endometriosis of the ovaries, led to hysterectomy. In the sections the endometrium was represented by an irregular disorganized layer scarcely thinner than normal endometrium. A round-celled deposit was abundant, glands were wholly absent and hyaline areas in the deepest layers and in the adjacent muscle were very obvious. The ovary on the other hand, remained healthy, vascularized but without distinctly normal ova. A small part of the endometrial mucus was seen in the section showed no degeneration. The difference between these sections suggested that the radium acted as a local and caustic agent on the endometrium.

The President asked whether it was generally believed that the action of radium introduced into the uterus was on the endometrium, or on the ovaries. Professor B. BELL asked what was the dose of radium given. He said that Dr Forsdyke had proved that the action of the radium was produced by its destruction of the endometrium. Professor MISS PHILLIPS said that he had three specimens removed after a radiation, which he had lent to Dr Forsdyke, and which proved that radium exerted a destructive action on the endometrium and not on the ovaries. Dr LEITH MURRAY said that he did not know the dose of radium used, it was said to be a "full sterilizing dose."

#### Foreign Bodies in the Genital Passages

Mr LEVINSON ROBINSON (Liverpool) showed the following specimens: (1) A taper and a crochet hook he had removed from the uterus in two cases of self-induced abortion. (2) A foreign body he had extracted from the vagina of a puerous woman, seven months pregnant. The patient sat down violently on a pot of vaseline, which entered the vagina and became imbedded in the upper part of the vagina, requiring an anaesthetic for its removal. (3) Two men, showing injuries to the cervix, from fatal cases of criminal abortion, alleged to have been procured by knitting needles. Mr ROBINSON said that these specimens were intended to emphasize the importance of careful pathological investigation in cases of suspected criminal abortion. It was necessary to demonstrate the fact of pregnancy, and also to prove that a suspected injury was neither accidental in origin nor the result of disease. These points could only be determined by experts, and it was essential that the type of case should be submitted to a gynaecologist and a pathologist in addition to a medico-legal expert, who might be neither.

The President said that it was very difficult to decide what should be done from the legal point of view when one

was called in to similar cases. Dr DONALD asked what was the coroner's verdict in the two fatal cases of criminal abortion. In a similar case which he had treated, the patient died, and there was a verdict of *felo-de-se*. Professor B. BELL said that he had once had three cases of septic abortion at the same time which had all been procured by one person whose name was given, all the patients recovered. He placed his evidence before the medical officer of health, who made investigations collected evidence, and eventually stopped the activities of that particular person. Dr McMEYER said he had had two fatal cases, but in which he had informed the police. Mr J. W. LAND ROBINSON in reply said that the verdicts in the two cases were respectively (a) septic abortion and (b) septic abortion following self-inflicted injury. In a local discussion Mr Justice AVERY had said that the police should always be informed. The British Medical Association had stated that the patient should be persuaded to inform the police. In practice he thought that if the patient recovered nothing was said.

#### Uterine Inversion

Mr S. GEORGE WILSON (Liverpool) showed a specimen of complete inversion of the uterus.

The patient aged 30 was a three-gravida. A healthy male child was delivered with the breech presenting. Twenty minutes afterwards compression of the uterus was employed for bleeding when the whole uterus and part of the vagina became inverted. The placenta was almost separated, it was removed and the fundus uteri drenched with hot lotion till it retracted. A tentative attempt at a reposition failed and the patient was treated with morphine grain 1/4 saline solution and warmth for moderate shock. She died three hours later. The specimen consisted of the pelvis with the uterus and the vagina inverted showing the broad and infundibulo-pelvic ligaments greatly stretched and the ovaries and tubes out of sight in the cavity of the inverted uterus. There was no intraperitoneal bleeding and the bottom of the pouch of Douglas was markedly raised.

Dr F. H. LACEY (Manchester) also read notes of a case of inversion of the uterus.

A primipara aged 23 was admitted to hospital suffering from an acute inversion which had occurred ten hours previously after an apparently normal labour. The midwife expressed the placenta when the inverted uterus was noticed. The patient was in a condition of profound shock. After treatment of the shock some hours later an attempt at reduction was made but failed owing to oedema. Averting a reposition was tried and failed. The patient had pre-eclampsia for three months and had white leg. She suffered from menorrhagia and was in very bad health. Nine months later he was better an attempt was made at replacing the uterus by inverting the cervix and anterior wall of the uterus. This failed until sutures were put in the fundus of the uterus and were pulled up through an abdominal incision. Then the uterus was easily replaced and the patient made a good recovery.

Professor MILLS PHILLIPS quoted the following figures of 184 cases collected from the *Lancet* and *British Medical Journal* up to 1912. 43 patients had died (23.4 per cent). Of the 171 who died without treatment of any kind, usually before the arrival of a medical practitioner. Of those in which the condition had been left unredressed often undiagnosed and treated as chronic inversion there were 49 cases of whom two patients died of sepsis (4 per cent). The body of the uterus had been twisted off and torn away by the midwife in two cases both patients recovered. In the case of immediate replacement the figures were as follows:

	Cases	Death	Percentage
Marked shock	79	24	30
No shock	23	0	0
Shock not mentioned (probably absent)	11	0	0

Replacement had been deliberately postponed until the shock had passed off in the case of one patient who recovered. In the *Lancet* and *British Medical Journal* 1912-1926 there had been recorded 34 cases four patients died (11.8 per cent) one of these before the arrival of a medical practitioner. Seven cases had been left unredressed some undiagnosed they had been treated as chronic inversion without any fatality. The figures for immediate replacement in this series were as follows:

	Cases	Death	Percentage
Marked shock	6	3	57.5
No shock	9	0	0
Shock not mentioned	3	0	0

Replacement had been deliberately postponed until recovery from shock in 7 cases without death ensuing in any of them. Professor PHILLIPS thought that treatment of shock was essential before making an attempt at reposition. Miss KINGS said that she had seen a patient who had suffered from inversion twice. The PRISONER stated that he had seen three cases, one of which had been followed by puerperal sepsis and later by death due to intestinal obstruction caused by adhesion of a loop of intestine to the fundus of the uterus. In reply Mr WILSON and Dr LACEY said that they thought the shock was due to stretching of peritoneum, with possible compression of the ovaries in the inverted uterus and the treatment in the first place was that of the shock.

#### Concealed Accidental Haemorrhage

Mr W. W. KING (Sheffield) read details of a case of concealed accidental haemorrhage treated expectantly.

The patient aged 46 was eight months pregnant with her twelfth child. Fourteen hours before admission to hospital she suffered from faintness, repeated vomiting and acute abdominal pain. On admission she was extremely ill, the face was pallid, the mouth and tongue were dry and the respirations were short, jerky and rapid. The pulse uncountable at the wrist was 120 at the apex beat. There was a cloud of albumin in the urine. The uterus was tense, hard and tender. The patient who was a hopeless surgical risk was given 500 ccm of defibrinated blood and 20 ccm of thromboplastin and the blood pressure soon after was 100 mm of mercury. Two hours later the blood pressure was 80, she was given another blood transfusion and the blood pressure rose to and remained at 100. Labour then started and she was delivered in four hours of twins, with two pounds of blood clot. There was no post partum haemorrhage and recovery was uninterrupted.

In a paper read recently before this Society Mr KING had called attention to the fact that in concealed accidental haemorrhage the uterine muscle showed no histological evidence of disease or degeneration, and that it was functionally active and capable of strong contractions. The present case supported the fact of the activity of the uterine muscle and of the possibility existing in the expectant method of treatment of cases of concealed accidental haemorrhage.

Professor F. F. GUNN asked if the blood platelets had been counted in this case. He had found that they increased in number after confinement up to the eighth to tenth day. Dr WILLIAMS believed that treatment should be expectant, though he had performed Caesarean section in one or two cases. Mr KING in reply, said that the blood platelets had not been counted.

#### Squamous Carcinoma of the Uterus

Dr LEITH MURRAY (Liverpool) described a case of squamous carcinoma of the cervix occurring five years after removal of the appendages. He first saw the patient, who was then aged 36 and a nullipara in March, 1922, and removed both appendages for bilateral hydrosalpinx and bilateral cystic ovaries, together with a small subserous fibroid. In June 1926 she complained of bleeding for three months, and was found to have a cauliflower growth of squamous carcinoma arising from the cervix which filled the upper part of the vagina. An extended Wertheim's panhysterectomy was easily performed and two months later an application of radium was given. In six months there was a serious recurrence with ulceration into the rectum and she died five months later. Dr MURRAY asked if there was any direct connexion between the removal of the appendages and the development and degree of malignancy. He considered that the cauliflower type of growth was more favourable from the point of view of operability and prognosis.

Dr DONALD recalled a patient who had had both ovaries removed, she complained of vaginal bleeding and he performed a vaginal hysterectomy. She had had no recurrence in six years. He was of the opinion that the cauliflower growth was the most malignant and Dr J. E. GEMMELL agreed.

Dr LEITH MURRAY in reply said he was amazed at the early recurrence as there was no thickening in the broad ligaments and it was a very easy operation to perform. He then reported a case of columnar and squamous

carcinoma coexisting in a uterus. The patient was a multipara aged 53, in whom the menopause had occurred eighteen months previously. For four months she had had a foul blood stained discharge. The uterus was enlarged and there was a nodule on the cervix believed to be a small retention cyst. A total hysterectomy had been performed four and a half years ago. She had had four treatments with radium and had no recurrence. The specimen showed two different types of tumour: (1) a fungating growth in the corpus and (2) a dense infiltration extending from the external os upwards for two and a half inches. Above there was a columnar carcinoma typical of that in the body, while lower down was the usual squamous celled carcinoma with massive processes of squamous cells surrounded by considerable round celled deposit. The nodule of the vaginal cervix was obviously an area of squamous carcinoma not yet broken down.

#### *Organismic Infection*

Dr C. P. BURNSTAN (Manchester) exhibited a specimen of *Organismic Infection* in the uterus. The organ removed by subtotal hysterectomy presented two small tubercles, one on the summit of the fundus, and the other near the right cornu. There was a strong band two inches long from the tubercle on the fundus to the cornu. On section the tubercles were found to be soft and homogeneous, and microscopically each showed the presence of a female *Organismic Infection* surrounded by a very large number of cells. The patient had had an abdominal operation for prolapse eleven years previously and a vaginal operation for prolapse one year ago.

Mr A. GORDON led what symptoms led to the hysterectomy and Dr BURNSTAN replied that the patient complained of menorrhagia and he had found that the uterus was retroverted and fixed.

### PREGNANCY AND PARTURITION WITH CARDIAC DISABILITY

At a meeting of the Liverpool Medical Institution on October 27th Dr JONES HILL and Dr LIZARD HILL contributed jointly a paper on pregnancy and parturition in patients with crippled hearts. The paper was based on a record of fifty consecutive cases, and its object was to correlate the dangers and difficulties of pregnancy and labour with the disabilities and disadvantages of valvular disease. In these cases the degree of valvular disease was greater than is usually met with in general practice. The fifty cases included 13 primiparae with three deaths, and 37 multiparae with two deaths. Mitral stenosis was present in 47 cases and in 8 patients there was, in addition, some aortic regurgitation. Five patients were suffering from mitricular fibrillation superimposed on the valvular disease. The problems discussed in the paper were as follows: the advisability of marriage in the presence of valvular disease, the termination of pregnancy in the event of conception, the manner in which pregnancy should be terminated, the best methods of affording relief during the stress of labour, and the management of the patient after the birth of the child. Consideration of the series showed the remarkable value of careful ante-natal treatment, which lessened the extreme distress during pregnancy and robbed labour of many of its dangers. In the case of the five deaths, four patients had manifested indications of nephritis, which had come on shortly before labour, and was the factor responsible for death. A necropsy was obtained in two cases, and the nephritis was found to be of recent origin and of the parenchymatous type. It appeared that women with advanced mitral disease were liable to develop a typical form of parenchymatous nephritis as the result of pregnancy, and that this manifested itself late and greatly increased the gravity of the outlook. The record of these series of cases demonstrated the wonderful way in which patients responded to care and efficient treatment, and justified the taking of a much more hopeful view in dealing with this type of case than the one commonly accepted.

## Reviews.

### PRACTICAL PYELOGRAPHY

SINCE Voelcker and Lichtenberg carried out the two first successful pyelographies in 1906 great strides have been made in this method of renal investigation, and what was at first merely a curiosity in medicine has now become a widely used method of diagnosis. Dr ALEXANDER E. ROCHE's work on the subject will, therefore, be of great use to the many surgeons who are now practising pyelography and who desire an up-to-date treatise on the subject. In his preliminary chapter on the history of pyelography the author deals with the various solutions that have been employed for the purpose of outlining the pelvis of the kidney. Most of the work on which the book is based has been carried out at St. Peter's Hospital, and after trying various solutions the author has come to the conclusion that a 12 per cent solution of sodium iodide is to be preferred. But although sodium iodide is ideal in many respects, it lacks the antiseptic properties of sodium bromide and thionium. In order to make good this deficiency a 1 in 3,000 solution of mercuric iodide may be added. Stress is laid on preliminary aspiration before the injection of fluid, and great gentleness during the injections. If no pain has occurred after the injection of 10 ccm the author recommends that a picture should be taken in order to ascertain the degree of filling as a guide to the amount still required for injection. Provided scrupulous care be observed in the carrying out of pyelography, the method may be employed with a minimum of danger in all patients except those suffering from acute or severe chronic urinary sepsis, or from renal insufficiency.

Perhaps the most necessary adjunct of pyelography is that the surgeon should possess a thorough knowledge of the appearance of the normal kidney and of the varieties of pelvis and calices that may occur. For this reason Chapter 1, dealing with the normal renal pelvis, is probably the most important in the book. It is in mistaking a normal variation pelvis for an abnormality that the inexperienced pyelographer usually goes astray, and we commend this chapter to his careful consideration. The concluding chapters deal with pyelographic appearances in such lesions as hydronephrosis, nephroptosis, neoplasm, renal infections, and congenital defects. To illustrate these various conditions excellent plates have been appended. In the selection of the pyelograms for reproduction judgement has been shown, and the text has been written throughout with commendable clearness. Finally, for those requiring further knowledge on the subject, a bibliography of the authorities quoted in the text is appended.

Dr Roche's book is, we believe, the only British monograph on the subject, and it is fortunate that it has been written by one who is capable of clear expression and methodical arrangement and possesses excellent judgement. The pyelograms scattered throughout the book are excellent, and both the author and publishers are to be congratulated on its general turn-out. Altogether the book should be a welcome addition to the library of those who are interested in pyelography, and even those who are not capable of carrying out such expert manipulations will find in its pages much that will be of interest and value.

### THE TEMPERATURE IN TUBERCULOSIS

IT IS AN AXIOM in medicine that the earlier a disease is recognized the better the chance of effecting a cure. It is for this reason that so much attention has been directed in recent times to the early diagnosis of disease, and it will be generally accepted that in no disease is early recognition of more importance than in tuberculosis. The little book on *The Significance of Temperature Variations in*

*Pyelography its History Technique Uses and Dangers* By Alex. E. Roche M.D. F.R.C.S. Eng. With an introduction by Sir John H. K. Lewis and Co., Ltd 1927 (Demy 8vo)

*Tuberculous Disease*, by Dr P C VARIER-JONES, contains a study of continuous temperature records of man in health and disease, and of cattle after the injection of tuberculin.

The book is really divided into three parts. The first deals with the mechanism of instruments for recording continuous and quasi-continuous temperatures, and the second with the application and value of such charts especially in tuberculosis; the third part (Chapters 10 and 11) is a history of thermometry. The thermometer first used by Dr Varrier-Jones was an essential that devised by Gingeo, but later this was replaced by the electrical resistance thermometer of the Cambridge Scientific Instrument Company. The description of the instruments makes tedious reading and is not easy to follow.

The medical practitioner will wish to know something of the practicability, portability, cost, and usefulness of the apparatus, but on the first three points little or no information is given; nor are we told whether the patients object to its application for twenty-four hours in the groin or rectum.

The fourth chapter, in which normal temperatures are discussed, contains nothing novel but is a record of the opinions and observations of others, though it is illustrated by some of the author's own charts. The fifth chapter deals with tuberculosis and in it is defined a continuous temperature curve characteristic of tubercle. This curve which can be produced by exercise or tuberculin, is said to be characterized 'by a more or less rapid rise of temperature 99° or more, a temperature which remains above 99° for a period of eight to twelve hours, the plateau commencing usually, though not invariably, about 2 p.m. and extending until 10-11-12 o'clock at night or even later when there is usually a sudden fall often with but sometimes without a night sweat.' This statement seems to contain the gist of the thesis maintained in the book.

The tuberculin test for cattle receives some attention, the author thinks that after injecting tuberculin it is easy to miss a rise or fall when the temperature is taken every four hours. Although this example is used to demonstrate the value of the continuous method, it does not seem to be suggested that veterinary surgeons should provide themselves with this complicated and delicate instrument for the purpose of making these tests.

A chapter is devoted to the value of the method in the early diagnosis and in the course of tuberculosis; it is well illustrated by many histories of patients in which temperature charts are reproduced but it affords no real evidence that in early cases there are changes in the temperature before other physical signs are obvious.

Continuous temperature records may be of considerable scientific interest, but we believe that outside a laboratory or hospital they are not yet practicable. That they give information of value is obvious since the highest and lowest temperatures of a patient in the twenty-four hours are rarely brought out by the ordinary thermometer. After reading the book we are left with the impression that the method is still in its infancy. The apparatus is complicated, requires to be standardized and is cumbersome, and experience has taught that it is not without inconvenience to the patient. Unfortunately the book is not easy to read with comfort; the meaning is often obscure—for example the following is typical. Speaking of characteristic curves the author says:

A sudden fall is looked on as not only associated with the night sweat but with the exhaustion of the patient induced by the tuberculin reaction, a process quite distinct from the disappearance of the prexia or the formation of a well defined cavity the result of softening and the evacuation of the caseous material—the tuberculinizing centre.

Nevertheless Dr Varrier-Jones makes some good points, and we would especially draw attention to the changes in the temperature curves in tuberculosis as the disease advances.

*The Significance of Temperature Variation in Tuberculous Disease*, by P. C. Varrier-Jones, M.A. Cantab., M.R.C.S., L.R.C.P. London: Cambridge University Press, 1927. Pp. 111. 6s. net.

## MACLEAN ON DIABETES

Of the successful series edited by Professor HUGH MACLEAN, of 'Modern Medical Monographs,' the first by himself on *Modern Methods in the Diagnosis and Treatment of Glycosuria and Diabetes* was brought out in 1922, and is now in a fourth edition, a testimony to its popularity which almost absolves the reviewer from further comment. The revision of this edition provides the conclusions to be drawn from the more prolonged experience of the use of insulin. In connexion with the types of diabetes there is no doubt about the advisability of giving insulin to severe cases, cases with coma, and when in spite of diet ketonuria and well marked glycosuria persist, or about its danger in renal glycosuria, but there may be difficulty in deciding about mildly patients with much glycosuria though little or no ketonuria, in such circumstances the occurrence of any eye changes is an indication for insulin, as otherwise blindness may supervene. In cardiac degeneration and angina pectoris the employment of insulin is attended with great danger, and, if given at all, great care must be taken not to render the urine sugar free, for a mild hypoglycaemia might set up angina which is very likely to prove fatal. Professor Maclean points out that the anginal pains that patients have previously experienced may be mild, and that nevertheless, many tragic results have followed the free administration of insulin to such patients.

The pancreatic preparations for oral administration which at present are flooding the market have been found to be without any effect on diabetes. The most recent preparation for oral administration, the synthetic product synthulin undoubtedly diminishes the glycosuria and ketosis in some diabetic patients, but it has well marked toxic properties, and the gastro-intestinal and other disturbances thus excited prevent its use at present, possibly a somewhat similar product without these objectionable properties may be produced, in the meanwhile however, insulin must be regarded as the only useful substance in the treatment of diabetes. Such is Professor Maclean's opinion, and it will have great weight with the clinician.

## CORONERS' LAW

It is almost a hundred years since Sir John Jervis compiled his treatise on *The Office and Duties of Coroners*. The task of bringing the book up to date, in accordance with the Coroners (Amendment) Act, 1926, which came into force last May, has been undertaken by the coroner for the Liberty of the Tower of London, Mr F. DANFORD THOMAS. He found the work of correlating the various Coroners Acts no easy one, and the difficulties were increased by the number of rules and orders which have been issued recently. The first part of the book contains the Coroners Acts of 1887, 1892, and 1921, the Amendment Act of 1926, the Infanticide Act of 1922, and the Births and Deaths Registration Act of 1926, explanatory notes are appended to many of the sections of the Acts. Mr Danford Thomas then gives a very full account of homicide in all its forms, quoting numerous cases in which judges have laid down law and established precedents. Many of these pronouncements shed an interesting light on legal psychology, and though no doubt, in general effect the principles are sound, in individual cases they must lead sometimes to curious inequalities of justice. In this connexion decisions that have been given in deaths during medical treatment, and from accidents on the highway, provide food for thought. At the conclusion of this portion of the book, the editor describes an historic inquest on a policeman killed in a Christy riot in 1833. The public was so pleased with the coroner's jury for finding a 'glorious verdict of justifiable homicide,' that silver cups were distributed to the seventeen jurors. One of these cups is now in Mr Danford Thomas's possession.

*Modern Methods in the Diagnosis and Treatment of Glycosuria and Diabetes*, by Hugh Maclean, M.D., D.Sc., F.R.C.P. Modern Medical Monograph. Fourth edition revised. London: Constable and Co., 1927. (Demy 8vo pp. 21 + 212, 10 figures, 13 charts. 12s. net.)

*Sir John Jervis on the Office and Duties of Coroners*. Seventh edition edited by F. Danford Thomas, M.A. Oxon. With an historical introduction by F. J. Waldo, M.A., M.D. Cantab. London: Sweet and Maxwell Ltd. and Stevens and Son, Ltd. 1927. (Roy. 8vo pp. xvi + 354, 2 plates. 11s. net.)

It appears that Sir John Jarvis was responsible for the opinion that coroners were *ex officio* justices of the peace. In this he would seem to have been confusing "conservators of the peace" with "justices of the peace" as at present understood. The Coroners' Society has stated that in its opinion "a coroner should not act as a magistrate unless specially appointed and sworn in at quarter sessions." An interesting historical introduction to this seventh edition of Sir John Jarvis's book has been written by Dr J. J. Warne, coroner of the City of London, in which he traces the origin of the ancient office of coroner and describes the powers and duties of the various kinds of coroner still existing or recently abolished. Since the passing of the Coroners (Amendment) Act Dr Warne becomes one of very few remaining authorized "franchise" coroners. If and when the King relinquishes the power to appoint coroners for the Isle of Wight and the Duchy of Lancaster Dr Warne will share the distinction with the King's coroner, the coroner of the King's Household, and the coroner for the City of London.

It is naturally too early to expect Mr. Dunford Thomas to express an opinion on the working of the Coroners (Amendment) Act. But there is one point to which Dr. Warne drew attention at a recent inquest. Discretionary power is now given to coroners, in cases of sudden death from unknown cause, to order a *post mortem* examination, and it is tied with the cause of death suggested by the doctor to dispense with an inquest. Dr. Warne stated that his experience in the past twenty-seven years had convinced him that in such case of sudden death the public interest would be served by a full inquest followed by a public inquest in the presence of the relations with the doctor and a jury on oath. A jury might generally in these cases be dispensed with, but the relatives would be given the opportunity of examining the witnesses, and would be unable to feel that they had a grievance. In his comment on the discretionary power Mr. Dunford Thomas says that "it will throw grave responsibility upon the coroner, and not only will equally careful inquiries have to be made by the coroner's officer of all persons about the deceased at the time of death and the circumstances generally, but the coroner should as far as possible make himself acquainted with the character, attainments, and reputation of the deceased in his district, and it would be undesirable to allow *post mortem* examinations to be conducted at private houses, and further as the report from the medical man is not to be given on oath and in inquest held it is better in known or suspected cases to have the examination made by a medical man in attendance on the family, but circumstances alone would determine whether this course should be followed generally." It would seem therefore, that the wise coroner will not make much use of this discretionary power.

Mr. Thomas Ottawa's *Law and Practice relating to Coroners* is a compact and complete little textbook of the special knowledge essential to coronership. The general reader will also find much interesting information in the book. Thus he will learn that in outlawry, which is now obsolete in practice, it is the duty of the coroner to attend at the final court and pronounce judgement of outlawry against a defendant in default, and that while a man is "outlawed," a woman is "wived." Sunday is a lawful day to the coroner for ministerial acts, but not for judicial duties. He may hold an inquest in the open air if necessary, but not on licensed premises where other suitable premises have been provided for the inquest. Treasure trove is, as a general rule, returned by the Lords of the Treasury to the finder, provided that he has reported his discovery promptly, and handed over the treasure to the proper authorities, but coins and other objects required for national or other institutions are retained, and the finders receive such sums as the institutions pay as the antiquarian value of the objects, less a percentage deduction. Mr. Ottawa describes the fineness of the line between murder and manslaughter, whether the provocation received is sufficient to reduce

the charge to the milder finding, whether, in fact, the provocation is such as would deprive a reasonable man of self-control. Another word in which fineness of distinction has recently become emphasized is "negligence." The development of motor traffic, by increasing road accident, has made the definition of negligence necessary for the purpose of sustaining a finding of manslaughter. The negligence must have been gross, wilful, and unlawful, with absence of all reasonable care, and something more than mere inadvertence. For the motorist, we are afraid, homicide is somewhat of a gamble, since, in the absence of any authorized rule in driving, the definition of negligence is subject largely to the mood and inclination of the judge. Mr. Ottawa's book, being a textbook, contains very little in the way of expression of opinion.

#### MALARIA IN INDIA

Our output of published work, the result of observation and research in India, yearly becomes larger in amount and greater in importance. Among the number of valuable books which have appeared during the current year the volume on *Malaria in India*, by Major General Sir Patrick Hehir, stands by itself, perhaps in that in the width of its scope it forms a monograph for reference, while in its practical detail it will serve as a textbook for the malariologist in the field.

In the preface the author states that the new volume has grown out of his *Prophylaxis of Malaria in India* (1910), which, revised, enlarged, illustrated, and brought up to date is incorporated with it, and he invites particular attention to the sections on the economic and sociological questions connected with malaria in India and the economic problems concerned with quinine. The book is indeed the author's message to India, after twenty-five years' work on one of her biggest problems.

The scope of this work may be gathered from the arrangement of its contents. Part I (pp. 1-177) is divided into sections on the prevalence of, mortality from, geographic distribution of, contributory causes of, personal predisposing cause of immunity to, role of man in the distribution of malaria in India, epidemic and incidental malaria, the human malaria carrier, Indian anophelines and their habits, the malarial parasites of man, and includes a malaria map of India created by Lieut. Colonel Christophers. In Part II (pp. 177-242) the malarial fever, the clinical and chemical pathology, and the pathological anatomy of malaria, together with the treatment dealt with in Part III (pp. 245-450) are discussed. Methods of prevention of malaria in India, segregation of the healthy, isolation of the infected, notification and lethal measures, with a very full discussion on the control of quinine. The subjects next in order are mosquito control in detail from various aspects, with special sections on malaria prevention in towns, in villages, in schools, houses, in military encampments, in jails, in industrial works, and in the individual, with, lastly, chapters on malarial surveys, education, expenditure, and economic sociological questions connected with malaria in India.

Throughout the author refers to the investigations and writings of others, so that with his own observations and criticisms we have a most comprehensive treatise on the whole subject, and one brought well up to date in sections.

Without attempting to go into detail we may refer to two sections to which the author has himself called attention. The question of the provision of quinine or a similar product in sufficient quantity and at a sufficient low price is a problem of the first magnitude when considering the treatment of the cases of malaria which annually in India. They are estimated to number hundreds of millions. Sir Patrick Hehir urges that, until time is some synthetic product may replace quinine, the Government should own cinchona plantations, co-manufacture and regulate the distribution and sale of quinine. The chapter on the economic and sociological ques-

connected with malaria in India is extremely interesting. Malaria in India is not a problem to be measured by so many pounds of quinine, so many yards of mosquito netting, so many chains of drains, or so many gallons of kerosene—it is a problem bound up with the general rural economic conditions in the widest sense, with the people, their habits and customs. The author's rapid survey of these conditions gives evidence of a lack of understanding of some of these big problems in the government of India in the past, but at the same time gives comfort in that "excellent foundations are being laid" which "will produce results that will surprise the people themselves within the present generation."

We have alluded to this book as the author's "message to India." The principle underlying that message—namely, that it is the duty of Governments by investigations along the widest lines to understand the peoples they govern and their conditions—is a message of the greatest importance to the world.

### NOTES ON BOOKS

A SMALL volume containing tables of foodstuffs compiled by Drs HERMANN SCHALL and AUGUST HEISLER of Königsfeld, has been received. It contains such particulars as the protein, fat, carbohydrate, water, and calorie content of animal and vegetable foods, drinks, made dishes, patent foods, infant foods, and diabetic preparations, the nutritional requirements according to bodily measurements in both sexes, and the amount of vitamins, cholesterol, cellulose, lecithin, purin bodies, and mineral substances contained in various articles of diet. The tables are numerous and the volume seems to have no exact counterpart in English.

*How to Feed the Family* is a little pamphlet written by Colonel P. B. LEEHAN, professor of public health in the University of Edinburgh and issued at 6d. by the People's League of Health, 12 Stratford Place, London W.1. Professor Leeahan, in simple language, compares the human body to a motor car which requires fuel, oil, electricity, and repairs, just as the body requires warmth and power, vitamins, materials for repair, salts, and water. Standard diets for a family equivalent to three men in which hearts, herrings, and corned beef figure largely are then given from which each individual may obtain the requisite 3,000 calories at a total cost of 19s. 8d. to 25s. 6d. a week. The prices stated for various foodstuffs are those obtaining in Scotland, but a list of the more important English variations is given from which it is interesting to learn that oatmeal is cheaper in England. The pamphlet should be useful.

*The Book of the Words of Tobit* has been brought out in an attractive form with a well-written introduction occupying more space than the Book of Tobit, with the scholarly pen of Mr. ERNEST H. SHORT who has also edited the book of Revelations. Tobit and his only son Tobias were regarded as harbingers of good fortune to the blind and in the fifteenth century many Tobit pictures were painted as votive offerings for blind men. Saint Lucia was regarded in the same way by women for no other reason. Mr. Short says that the verbal association of the name Lucia (light) with the organ of sight, though the legend arose that this beautiful saint plucked out her eyes because a young Roman, inflamed by their lustre, gave her no peace from his attentions. The book is well illustrated by plates from the old masters, which Mr. Short pleasantly describes.

Major A. J. DAWSON is a well-known devotee at the shrine of the dog, even as the Egyptian was at the shrine of the cat. Hence perhaps the copious libations of word in his *Letters to Young Dog Owners*. But his treatment of his subject is sound and the would-be dog owner will find concealed in the letters all that he can want to know in the care and training of dogs. It would appear that Major Dawson's presumably imaginary correspondent found him reticent on the subject of health in dog, meaning thereby the administration of medicine. The author hopes that his letters have insured the

reader against any need for dog doctoring, but he has failed to achieve the consciousness of a veteran dog breeder whom he quotes. This authority was asked by a newspaper editor (a) how to doctor dog, (b) for a general policy and methods in disease and illness in dogs. His replies were (a) Don't, (b) avoid em.

A Dictionary of Bacteriological Equivalents<sup>10</sup> in English, French, German, Italian, and Spanish has been prepared by Mr. W. PARTRIDGE F.I.C., and will be found useful by those who wish to study papers on bacteriology published in the foreign languages mentioned.

<sup>10</sup> Dictionary of Bacteriological Equivalents. By William Partridge F.I.C. London: Baillière Tindall and Cox, 1927. (Post 8vo pp. xii + 341. 10s. 6d. net.)

### PREPARATIONS AND APPLIANCES

#### EPHEDRINE AND SYNTHETIC EPHEDRINE (EPHETONIN)

A DESCRIPTION of the physiological action of ephedrine, obtained from *Ephedra vulgaris* var. *helvetica* by Dr. K. K. Chen of the Union Medical College, Peking, was published in our columns on October 1st (p. 593). It was then mentioned that the drug had been found useful in asthma as a bronchodilator. Ephedrine acts like adrenaline but has the important advantages that it can be given by mouth and exerts a much more prolonged action than the latter.

Messrs. E. Merck have recently placed on the market a synthetic product which they state is identical in chemical constitution with natural ephedrine—that is to say, it is phenyl methyl amino propanol hydrochloride ( $C_{11}H_{15}NOHCl$ ). It is described as synthetic ephedrine and has been given the trade name ephetonin. The vendors claim that experimental and clinical trials have shown that ephetonin produces the same action as ephedrine. The production of this drug in a synthetic form is an interesting advance in science. The London agents are Messrs. H. R. Knapp, Ltd., 3 and 4, Clements Inn, Kingsway.

#### RUBBER SURGICAL GLOVES

Messrs. Allen and Hanburys (48 Wigmore Street, London, W.1) have sent us a sample of India rubber gloves, manufactured, they state, by a new process, which renders the rubber extremely tough so that it may be subjected to sterilization under high pressure steam. They claim that as the rubber is tougher a thinner glove can be used. The price is 2s. a pair or 21s. a dozen. The gloves have been tested for us by a surgeon, who writes:

I have operated twice with the gloves and find them quite satisfactory except that their touch is not quite the same as that of the I am used to. I understand that these gloves are made in London by means of a new process of vulcanization of the rubber which renders them thin, tough and durable and better fitted to withstand repeated sterilization under high pressure steam than the American gloves. The new gloves owing to their greater durability should effect an economy for general use in hospitals and as they are of British manufacture I feel that they ought to be strongly and widely recommended. I found them a little more slippery to the touch than the Miller (American) gloves I am used to, but the pair sent were a little too large for me. This would be obviated by more experience in using them. I understand that it is necessary to order a slightly larger size so that anyone wearing a 7½ would require an 8.

#### CONCENTRATED DIPHTHERIA ANTITOXIN

The Wellcome laboratories have for many years produced diphtheria antitoxin of a concentration of 1,000 units per cubic centimetre. Improvements in the separation of the antitoxin-bearing fraction of the serum have now made it possible to prepare a concentrated diphtheria antitoxin of 2,000 units per cubic centimetre. The achievement is indicated by the fact that only a minimal activity of 350 units per cubic centimetre for purified antidiphtheric serum.

#### A SIMPLE PLEXIMETER

Dr. I. Kovolman of Glasgow has invented a device made of vulcanite and shaped like a small spoon to serve as a pleximeter in percussion. The inventor claims that his use lesions can be more accurately localized in the chest and that it is very satisfactory in percussing the abdomen. He calls it the phalangoscope, and it is a simple device but in all pleximeters there must be some loss of that tactile sensation which is so informative in percussion when the finger is used. The apparatus is made by Thackray & Co., Great George Street, Leeds.

SATURDAY, NOVEMBER 19TH, 1927.

## PROSTATIC ENLARGEMENT

In his Bradshaw Lecture to the Royal College of Surgeons, published in the opening pages of this issue, Sir Cuthbert Wallace reviews the present position of our knowledge of prostatic enlargement. The condition is so common and so embarrassing to the sufferer, who is often overtaken by it while still capable of useful work, that the lecture will be read with great interest by general practitioners, for it discusses practical problems with which they are often confronted. It will also, we feel sure, be carefully studied by specialists, for to those who are so immersed in the details of some particular field of surgery, that they find difficulty in appreciating the chief landmarks it is of no little advantage when one with the experience of Sir Cuthbert Wallace mounts a podium and points out the main features of the landscape. In some directions much progress has been made in the study of prostatic enlargement, and fortunately this applies particularly to treatment, but, as the lecturer observes in his introductory remarks, our knowledge of the function and the pathology of the prostate remains more or less what it was at the end of the last century. Even when we come to the mechanisms of prostatic obstructions there is little that can be asserted with any degree of confidence. In Sir Cuthbert Wallace's opinion no satisfactory explanation has yet been offered of residual urine and of the deterioration of the function of the kidneys that results from the obstruction. His suggestion that residual urine is really a result of bladder posture is ingenious, but may not at once carry conviction. His theory is that if the act of emptying the bladder is slow or interrupted the impulse necessary for carrying it to completion does not arise. To some it will seem that this explanation exchanges one set of difficulties for another, we are still left wondering as to the cause that lies behind it all. In his effort to account for the ill effects of obstruction on the kidneys the lecturer, after showing that the commonly accepted view of back pressure is unsatisfactory, puts forward three possible explanations of the renal complications which follow, these are that the kidneys are extremely sensitive to any obstruction, that the damage done is in the nature of a sudden catastrophe, or that some cause must be sought for that is at present unknown. In other words, he has to admit that we are still completely in the dark.

It will be noticed that Sir Cuthbert Wallace lays very little stress on infection, either in speaking of the pathology of prostatic obstruction or in connexion with treatment. This omission, which was no doubt deliberate, is particularly striking when we consider that the chief direction the more recent efforts of operators have taken has been to attempt to reduce the harmful effects of infection on the convalescence of prostatectomized patients. Some surgeons believe that the chief danger of prostatectomy lies in the fact that it is of necessity a septic operation. In the hope of reducing this, new methods have been introduced with the object of allowing the field of operation to be

directly inspected, and tags of mucous membrane and torn tissue to be removed so as to prevent their forming a nidus on which organisms may flourish. In the lecturer's opinion these efforts to reduce infection would appear to be unnecessary, and he is even inclined to regard irrigation of the bladder and of the prostatic cavity with antiseptic fluids as inadvisable. The lesson that he would teach is rather that the less the prostatic couch is interfered with after operation the better. He attributes his comparative freedom from secondary haemorrhage to the fact that he only resorts to washing out the bladder in exceptional circumstances.

In speaking of mortality he showed that in his own hospital (St. Thomas's) the mortality from prostatectomy during the years 1922 to 1926 was 14.5 per cent, and that when with the prostatectomy mortality that resulting from suprapubic cystostomy was included it was as high as 22.5 per cent. Even if we admit that patients suffering from prostatic obstruction are usually bad cases for operation, and that they have too often postponed seeking relief until threatened with renal failure, prostatectomy must still be regarded as an operation attended with very grave risks. A study of the causes of death following operation shows that the majority of patients die as the result of not one, but of several complications, of which sepsis would seem to be the worst.

The lecture is provocative of thought, and we shall not be surprised if it gives rise to some controversy. We could perhaps have wished that Sir Cuthbert Wallace, in concluding this valuable survey of prostatic surgery, had indicated the direction in which future improvement is to be expected. However gratifying the progress that has been made since 1886, it is impossible to remain satisfied with the present state of affairs. We may hope that some future Bradshaw lecturer will be able to record an advance in prostatic surgery at least as great as that described by Sir Cuthbert Wallace.

## OXYGEN THERAPY

Our experience obtained during the war of the great value of oxygen in the treatment of gas poisoning did much to encourage its use in civil practice, and recognition of its importance as a therapeutic agent has increased considerably during the last decade. At the same time, it is notorious that the results of the therapeutic use of oxygen often are unexpectedly disappointing. Hence the papers on oxygen administration which appear in this number are of special interest.

The main principles which should govern the use of oxygen were set out clearly by Professor J. S. Haldane ten years ago.<sup>1</sup> Oxygen therapy is not likely to be found of much service unless these fundamental principles are clearly understood, and Dr. Whitridge Davis has done good service in restating them and in providing at the same time quantitative data which will facilitate their application in practice. The outstanding fact is, of course, that the normal alveolar air contains 14 per cent of oxygen, and that oxygen cannot be expected to produce benefit unless sufficient is given to raise this proportion by a significant amount. Dr. Davies has supplied us with figures showing the actual effects on the composition of the alveolar air produced by varying quantities of oxygen given by various methods. His analyses reveal the rather surprising fact that administration of oxygen through a nasal catheter is not

<sup>1</sup> Haldane, *BRITISH MEDICAL JOURNAL*, 1917, 1: 181. See also *JOURNAL*, 1919, 1, 65.

more effective than delivery into a funnel held over the patient's mouth, and hence some form of mask is essential if the use of the gas is to be effective. His results indicate that the smallest rate of flow likely to produce benefit is about two litres a minute and in this connexion he states that, when oxygen bubbles through water at the fastest rate at which the bubbles can be counted, the flow only corresponds to a quarter of a litre a minute, which is a quantity insufficient to produce any effect.

These conclusions are of great practical importance, for they suggest that the usual methods of giving oxygen are extremely inefficient, and further that the gas is very frequently given at a rate which would be too low to produce an effect even if the method of administration were efficient. The discussion on the paper suggested, however, the great need for careful clinical tests of these conclusions. Dr Hilton for example found that an oxygen flow of 0.75 to 1 litre a minute given by a nasal catheter might produce distinct benefit in certain cases.

The main physiological principles involved in the administration of oxygen are very simple, but the clinical applications of these principles are complex because of the great variety of the conditions that lead to anoxæmia. Even in a single disease such as lobar pneumonia we must assume that many degrees of impairment of the alveolar epithelium exist in those portions of the lung still functioning and it is probable that in some cases a very small rise in alveolar oxygen tension may just make the difference between sufficient and insufficient aeration of the blood.

An important point mentioned by Dr Ritchie was that in pneumonia the faintest trace of cyanosis in the lips, ears or nose is a call for oxygen. Professor Haldane has repeatedly emphasized the fact that oxygen should be given early before pronounced cyanosis occurs because severe cyanosis will quickly produce irreparable injury to the vital organs. Dr Davies did not discuss the use of subcutaneous injections of oxygen but it is difficult to understand how these can produce much benefit. In the first place, an adult at rest requires about a quarter of a litre of oxygen a minute and therefore the amount that can be introduced subcutaneously is negligible compared with the amount the body is using. In the second place the oxygen will be taken up by the capillaries and will only increase the oxygen tension in the local tissues and in the venous blood whereas the object of oxygen therapy is to increase the oxygen tension in the arterial blood which goes to the vital organs.

It is perhaps fair to say of our present knowledge of oxygen therapy that the main physiological principles involved are fairly well established and that what is chiefly needed is more clinical information based on accurate measurements to determine over what range of dosage oxygen can produce measurable benefit in actual cases of disease.

In his final paragraphs Dr Davies touches on another very important point—namely the possible value of oxygen in the treatment of chronic respiratory diseases. Professor Barcroft and his fellow workers produced very remarkable permanent benefit in patients suffering from chronic after effects of gas poisoning by treating them for a few days in an oxygen chamber. This method of treatment unfortunately is expensive as it involves a specially constructed chamber and large quantities of oxygen but a full investigation of its possibilities is obviously desirable in view of the serious economic loss caused by ill health due to chronic respiratory diseases in the adult population.

## TREATMENT OF RECTAL CANCER BY RADIUM

Radium has had an uphill fight for recognition, and may be said to have made good in spite of the enthusiasm of its early supporters many of whom advanced claims unjustified by the true facts. Recent developments—largely the outcome of the closely co-ordinated team work of some of the Continental clinics—have now placed radium therapy in such a position that, in regard to two or three at least of the common kinds of cancer it is beyond all question an important alternative to operative treatment.

Cancer of the cervix uteri and cancer of the lip and tongue have furnished so far the most convincing body of evidence as to the value of radium and although there is not yet complete unanimity—possibly owing to the fact that there are still some surgeons who have either not had or not taken the opportunity of seeing what is being done—there certainly is an ever increasing body of authoritative opinion in its favour, composed of those who have actually seen the results obtained in London, Manchester, Stockholm, Paris, Brussels and many other centres. All these successes would appear to have followed upon the introduction of the radium needles and the appreciation of the fact that in order to obtain good results the radium containing needles must be inserted actually into the substance of the growth, and must remain there a considerable time. It is easy to understand, therefore, that the more accessible the growth the better the results and that cancer in those situations to which access is difficult has not been attacked with the same energy and enthusiasm.

Cancer of the rectum has suffered in this way for not only are there considerable technical difficulties attending the mere insertion of the needles but an accurate estimate of the size of the growth is difficult to arrive at by the ordinary methods and in consequence the dosage is largely a matter of chance. On November 9th at a meeting of the Subsection of Proctology of the Royal Society of Medicine Sir Charles Gordon Watson described a method of radium treatment of cancer of the rectum by open operation. Briefly it consists in exposing the rectum by a posterior incision extending from the sacrum to the anus the coccyx being removed in order to allow adequate space for the manipulation necessary to estimate the size and extent of the growth and to assess the dosage indicated. The radium is employed in needles varying in length from 2 to 5 cm. which are so placed as to ensure that every part of the growth and its extensions receives a barrage of gamma rays of equal intensity. Roughly speaking the general aim is to ensure that every cubic centimetre of growth shall have at least 2 mg. of radium acting upon it for a minimum period of seven days. The method embodies, therefore, the general principle of a small dose for a prolonged period as opposed to the earlier and more general principle of a heavy dose for a short time. The speaker was able to show two patients in whom this plan of attack had been employed with such success as to cause complete disappearance of any evidence of cancer the growth having been replaced by a fibrous stricture.

This development of the surgery of access, which is now so important a factor in radium treatment is clearly of the greatest value and Sir Charles Gordon Watson is to be congratulated upon his enterprise and upon the success that has attended his efforts.
